OPERATIONS FOR URINARY CALCULI.

BY GEORGE E. POST, M.D., LL.D.,

BEIRUT, SYRIA.

PROFESSOR OF SURGERY IN THE SYRIAN PROTESTANT COLLEGE.

THE following tables are in continuation of those published in the MEDICAL RECORD of July 28, 1877, and October 30, 1880. The numbers are those of the author's case-book. The operation indicated by the name Post is described in the notes on the first of the above tables. By the Italian operation is meant the median perineal. Many of the smaller stones were removed from very short incisions, too small to permit of the entrance of the finger into the bladder. Many of them healed by first intention. In few of them was there any noteworthy hemorrhage. The Arabic operation is made by introducing one or two fingers into the rectum, prying the stone downward so as to make it prominent in perineum, and cutting down on it with a razor. The sphincter is frequently cut in this operation, leaving a fistula which is often incurable.

I.—VESICAL CALCULI REMOVED BY PERINEAL LITHOTOMY.

No.	Name	Age	Residence	Duration	Date	Operation	No. of Stones	Shape	Weight, Gms.	Return of Urine per Urethram	Analysis	Results
149	Michail	60	Damascus	4 years	Sept. 15, 1880	Lateral.	1	Long ovoid	96.	.....	Urates	Recovery.

NOTES.

149. This case was complicated with chronic bronchitis and fatty heart. There was considerable hemorrhage at time of operation, arrested by Liq. Ferri Perchloridi. On the 29th of October he left for his home. He had had troublesome diarrhea, which was cured when he left. He had, however, bedsores, and his bronchitis was still very troublesome. Wound not healed. No subsequent history.

154. Perineal fistula remained after operation. Wound was gradually contracting until two months after operation, when patient was taken with diarrhea after imprudence in diet, and died.

158. The father says that the boy passed two stones a year ago per urethram. In the meantime he was free from symptoms until four months ago.

159. Had a median operation done in infancy for a very large stone. The cicatrix of the old wound much corrugated. Has complained of symptoms of stone only one month. It is probable, however, that the stone was much longer in forming.

162. Hemorrhage. Tubed; packed with sponges saturated with perchloride. Patient died after six days of septicemia.

164. Opening into bladder only large enough to admit a dressing forceps, with which the stone was extracted.

187. Had had a bilateral lithotomy done in Damascus a year previous, and one stone removed. Symptoms of stone remained. No staff or sound could be passed into the bladder. A staff was passed to membranous urethra, the urethra opened, and a probe introduced into the bladder. A grooved director was then introduced into the bladder and the neck incised in median line and the stones removed.

204. Operation commenced as a litholopaxy, with a Civiale's fenestrated lithotrite. After considerably reducing the size of the stone the female blade snapped off in the bladder. The operation was completed by perineal section.

221. Several months before operation a surgeon had cut for stone, but did not succeed in removing it, only two fragments coming away in the grasp of the forceps. A perineal fistula remained, through which the stone could be felt. The stone, which was as large as a walnut, was tightly embraced by the empty bladder. The fistulous track was enlarged in the median line, and the stone grasped and crushed by the forceps, and extracted piecemeal.

274. The boy had a harelip, which was operated on at the same time.

277. This case was complicated with a stricture of urethra and scrotal fistula, both of which were cured by the operation.

284. Compare 335.

332. The stone was coated with a tough layer of inspissated mucus, which gave no click with the sound.

335. Recurrent from 284.

343. Owing to the roughness of the stone the rectum was torn during extraction from the neck of the bladder to the verge of the anus. The patient nevertheless recovered with a perfect rectum and perineum.

430. The stones were found in a pouch at the mouth of the ureter. On the seventh day there was secondary hemorrhage from the wound. The wound was tubed, and bladder washed, but no clots found. Two days later the tube was removed. On the twelfth day he passed a small stone through the wound, probably a fresh descent from the ureter. After this the wound was tubed for several days, but, as no more stones passed, was suffered to heal.

439. The nucleus weighed 1.3 gram, and was enclosed in a doughy mass of inspissated mucus, mixed with gritty matter, which gave out no sound on percussion with the searcher.

478. Stone of puttylike consistence, yielding scarcely any click on percussion.

481. Recurrent from 478. After the first operation the child passed puttylike masses of calculous matter, mixed with inspissated mucus. It would appear that some of this material formed the nucleus of the second stone. Further calculous formation was prevented by systematic irrigation of the bladder.

490. Calculus, triangular-pyramidal in shape, with sharp points, created great irritation, notwithstanding its small size, by pricking the sensitive neck of the bladder.

497. The stones were triangular-pyramidal in shape, with blunt angles.

521. Has a large hernia caused by straining. Urine in a stinking condition at time of operation. Died of exhaustion a month after operation.

NOTES.

304. Stitched bladder with three gut sutures; muscles with five gut sutures; skin with eight gut sutures. Drew water at regular intervals with catheter. Patient died on eighth day of septic peritonitis.

345. Drained bladder from lower angle of wound. Stitched remainder of wound in three layers—bladder, muscles, skin.

346. A previous unsuccessful attempt had been made by another surgeon to remove the stone by perineal lithotomy. Bladder drained from lower angle of wound.

363. Bladder drained from lower angle of wound.

379. Had uremic convulsions the night after the operation. Died comatose the following morning. Drained from interior angle.

407. Same treatment of wound as in 363.

412. Same treatment of wound as in 363.

422. Same treatment of wound as in 363.

424. Patient did well until fifth day, when the wound began to have a sloughy appearance. Died ninth day of exhaustion. No suppression of urine. The stones weighed 96., 57½, 5½, 3½, 1½, 1, and 1 grams.

437. Same treatment of wound as in 363.

440. Same treatment of wound as in 363.

452. Same treatment of wound as in 363.

454. Same treatment of wound as in 363.

459. Same treatment of wound as in 363.

463. Same treatment of wound as in 363.

464. The operation was commenced as a suprapubic. The stone proved to have a vesical portion which broke off in the forceps, and a prostatic portion which could not be delivered by the bladder, but was delivered by a median perineal incision.

466. Same treatment of wound as in 363.

474. Died on morning of sixth day of peritonitis. Drainage from inferior angle.

484. Same treatment of wound as in 363.

506. Same treatment of wound as in 363.

530. Same treatment of wound as in 363.

534. At six months of age had symptoms of stone. At two years of age was operated on by a surgeon in Damascus, but no stone found. A fistula remained in perineum. At three years of age another Damascus surgeon removed by perineal lithotomy a stone as large as last joint of forefinger. The fistula remained. Symptoms of stone remained worse than before. Between four and five years of age a third Damascus surgeon removed by perineal lithotomy six stones, of which one was as large as last joint of finger. Several perineal fistulæ remained. The writer, finding a stone encysted in the perineum, removed it by enlarging and connecting the fistulæ. Finding by rectal palpation a prostatic stone with a vesical prolongation, a suprapubic cystotomy was done and the stone extracted. The perineal cyst was exsected, and a tube .005 caliber inserted from the suprapubic to the perineal wound, and the remainder of the suprapubic wound sewed. Two weeks later the tube was withdrawn, the perineal fistula exsected, and a flexible catheter passed from the meatus to the suprapubic wound. The perineal tract then contracted and healed, and the catheter was withdrawn, and the suprapubic wound healed. The patient was discharged cured three months after the first operation.

535. Same treatment of wound as in 363.

537. Drained from inferior angle. Died three days after the operation of uremic convulsions. A postmortem showed no signs of infection of wound or peritoneum.

551. Same treatment of wound as in 363.

554. Same treatment of wound as in 363.

556. Same treatment of wound as in 363.

562. Same treatment of wound as in 363.

569. Same treatment of wound as in 363.

570. Same treatment of wound as in 363.

572. Drained from lower angle. Died twenty days after operation of diarrhea.

584. Same treatment of wound as in 363.

587. Same treatment of wound as in 363.

593. Drained from lower angle to, but not into, bladder.

595. Same treatment of wound as in 363.

596. Same treatment of wound as in 363.

597. Peritonitis set in second day after operation and ended fatally on fifth.

598. Drained only from lower angle of wound. Has been operated on three times by other surgeons perineally, leaving perineal fistula. Perineal fistula was closed thirty days after operation.

Notes.

153. Case published in full in El Tabib, June, 1881.

165. Recurrent from 160.

174. Died thirty hours after operation of uremic poisoning and suppression of urine. Had much tenderness over both kidneys at time of operation. No post mortem obtainable.

175. Recurrent from 151.

183. Recurrent from 180.

186. Has passed 150 kidney stones per urethram. The stones, crushed and evacuated, were small and numerous. Some small stones or nuclei were evacuated entire.

209. Recurrent from 197. Died with uremic symptoms and suppression of urine.

210. Recurrent from 202.

214. Recurrent from 210 and 202.

219. Died sixteen days after operation of uremic poisoning. At autopsy both kidneys were found hypertrophied. The bladder was closely contracted on a fragment as large as a peanut.

229. Had passed several kidney stones per uretheram before the present one was formed in the bladder.

234. Recurrent from 207.

236. Had constant dribbling of urine before operation. Was quite cured of this symptom after the litholapaxy.

237. Urine before and after operation loaded with pus and highly albuminous. No casts could be found.

248. Had been operated on by writer thirteen years before by bilateral lithotomy.

251. Died the seventh day after operation of uremic poisoning. No autopsy.

285. Seven months previous to the litholapaxy the patient had been cut by an Arab stonecutter and a calculus extracted.

326. Patient coughed during the whole operation. After two aspirations neither catheter nor sounds could be passed. As most of the stone seemed to be evacuated the operation was suspended. Three days afterward a mass of detritus was detected in the prostate, which prevented the passage of a sound. Perineal section was done, and five grams of detritus evacuated. Urine then flowed through perineal wound. Three days later patient became comatose and died. There was no suppression of urine.

334. Before the operation the patient had had incontinence of urine. After the litholapaxy the neck of the bladder gradually recovered its tone and the patient was able to retain his urine. A fortnight after the operation a lithotrite was introduced and detritus removed in its jaws, after which the instrument closed on something which I feared might be a fold of the mucous membrane. On withdrawing the lithotrite I found in its grasp a broom straw, an inch long, coated with phosphates. The patient confessed that he had introduced it three years before to excite erotic sensations. It had become the nucleus of the stone.

339. Nucleus of tinfoil, which seems to have been introduced for erotic purposes.

356. Fragments of elastic catheter, coated with sabulous matter.

372. Passes kidney stones. (See cases 389 and 406.)

389. Recurrent from 372. Same patient as 406.

394. Habitually passes kidney stones per urethram.

396. Recurrent from 355, May 4, 1896. Eight months after first crushing the patient was operated on by Dr. Hoffman, suprapubically, and a large stone extracted. The present stone, therefore, must have had a fresh nucleus.

397. A stone removed several years before by median perineal section. Has passed numerous stones per urethram.

406. Same as 372 and 389.

417. In this case the fragments were removed in the jaws of the lithotrite without aspiration.

418. As in last, removed without aspiration.

431. On second day after operation the penis was swollen and emphysematous with gas. On incising, the corpora cavernosa were found gangrenous. Diarrhea set in. On fifth day there was pain and tenderness in the region of the left kidney. On the ninth day he died. *Autopsy*: Purulent effusion along rectus abdominis muscle. Peritoneum not involved. Left kidney enlarged, with hemorrhagic patches in its substance. Small intestines intensely congested. Right kidney normal. Death from septicemia.

438. Was operated on suprapubically eleven years before by a surgeon in Cyprus. A ventral hernia as large as a cocoanut resulted. During the lithotrity the jaws of the lithotrite were frequently encumbered by shreds of rags, which had been used as tents during the after treatment of the suprapubic operation.

462. As in 417 and 418, removed without aspiration.

468. A year before had had a stone weighing 90 grams crushed by another surgeon. Symptoms of stone had continued, however, from time of operation. A nucleus of urates was found encrusted with phosphates, showing that the new stone was formed around a fragment of the old.

504. Recurrent from 458.

512. Fragments, not evacuated by the aspirator, became impacted in the urethra, causing urinary infiltration of penis and scrotum, and septicemia.

550. Passed a kidney stone several years before. Later had a stone removed from the urethra. Still later the present stone formed in the bladder.

553. Same as 564.

564. Same as 553.

576. Recurrent from 527.

590. Crushed half the stone, when the lithotrite gave out, and, not having another at command, completed the operation by median lithotomy.

IV.—STONES EXTRACTED FROM URETHRA IN MALE, INCLUDING PROSTATIC AND PROSTATICO-VESICAL STONES.

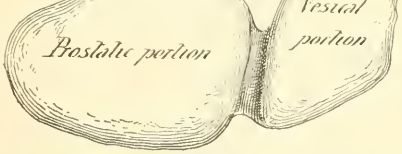
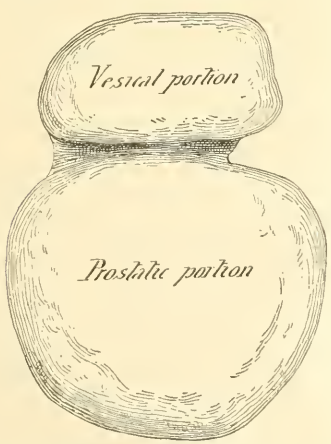
Notes.

170. In removing this stone the constriction at the neck of the bladder was divided in several places until the vesical lobe of the stone could be drawn into the perineal incision. There was severe hemorrhage from the vessels divided to provide for the release of the prostatic portion. They were tied. The peritoneum bulged into the wound posteriorly, but was not cut or torn. After the arrest of the hemorrhage the wound was packed around a rubber tube. In twenty-nine days the wound was healed and the patient discharged with perfect continence of urine.





244. The constriction at the neck of the bladder was incised at several places to release the stone. Wound healed in fourteen days, with complete continence of urine.

254. The patient had had phymosis, for which he had been circumcised. There was a stricture at the meatus, and an inch behind it a stone .005 long, .004 broad, .002 thick. It was removed, after incision of the stricture of the meatus, by means of Civiale's forceps. Five inches from the meatus was another stone, a little longer than the first. It was also removed by Civiale's forceps. A third was found in the bladder. The urethra was then dilated to 20 English, and the stone extracted without crushing. It was .006 long, .005 broad, and .003 thick. The patient had perfect continence of urine.

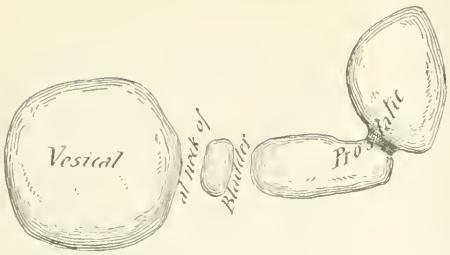
256. Three weeks before operation patient began to have retention. Ineffective attempts had been made by others to pass a catheter. Author succeeded in passing a catheter, but did not detect the stone, which was doubtless pushed into bladder. The catheter was introduced daily to draw the urine. After three weeks a stone came down to navicular fossa, from which it was extracted. It measured .003 x .002 x .001.

272. Stone impacted in bulbous portion of urethra. As it could not be removed either by scoop or forceps, the scrotum was drawn forward, and an opening made behind it into the urethra. The wound continued to dribble urine for twenty days, and then healed.

281. Pried with probe out of navicular fossa.

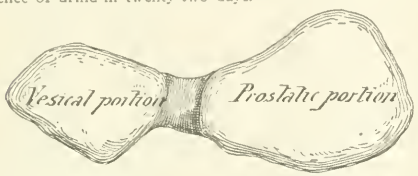
282. Pried out of navicular fossa, with grooved director.

287. Bladder stone weighed 11., that at neck 0.50, at prostatic 7.50. Patient recovered in twenty-five days, with complete continence of urine.



310. Crushed with dressing forceps in navicular fossa and extracted piecemeal.

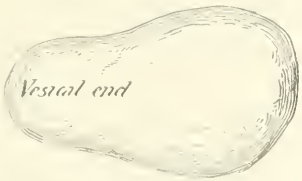
321. Prostatic portion weighs 11 grams, vesical 6.50. Broke at neck in extracting without nicking the constricting collar at the neck of bladder. Patient regained continence of urine in twenty-two days.



330. Broke down in extracting. Continence of urine regained second day after operation.

335. Three years previously the author had removed a stone (see Case 264) by median lithotomy. For two years patient remained well, but then began to have dribbling of urine. He then began to feel a small lump forming in his perineum. By median section two stones, articulating with each other, were found in prostate. Patient continued to dribble a little urine after operation.

338. Stone extended from neck of bladder to triangular ligament. Had no incontinence of urine, as bladder was not entered by the incision, which was lateral.



301. No incontinence. Bladder not entered

305. Impacted an inch behind meatus. Broken with fine forceps and extracted.

410. Fried out of navicular fossa.

434. Impacted in bulb. Removed with scoop.

456. Impacted at scroto-penal junction. Extracted with forceps. The same patient (Case 448) had had median lithotomy four months before, and a stone weighing two grams extracted from bladder.

457. Impacted at scroto-penal junction. Having failed to grasp with forceps or evacuate with scoop, on account of stone slipping back, made median section to triangular ligament, steadied stone with left forefinger, grasped with forceps, and extracted through meatus. Fistula closed in six days.

464. Operation commenced as a suprapubic. As it was found impossible to deliver the prostatic portion through the suprapubic opening, after it had broken off at the neck, a median perineal incision was made and the stone removed. The suprapubic opening was then sutured, and the perineal wound tubed.

465. Impacted in glans. Upper and lower aspects of meatus nicked, and stone pried out.

470. Removed by median incision. Continence of urine perfect after healing of wound.

473. Impacted in bulb. Scrotum drawn forward and stone cut down on and removed. No dribbling from wound.

476. Impacted in navicular fossa. Extracted with forceps.

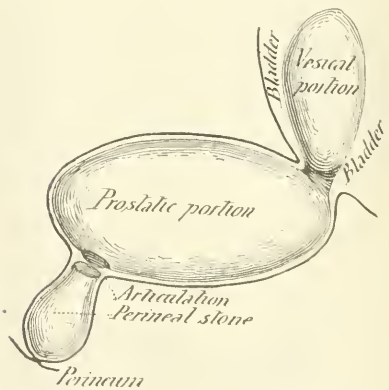
489. Impacted in navicular fossa. Extracted with forceps.

492. Impacted at peno-scrotal junction. Extracted with scoop.

495. Impacted in navicular fossa. Broken up by probe and pried out in pieces.

505. Impacted in navicular fossa. Incised meatus, hooked stone forward, and extracted with forceps.

509. Many years before a stone had been removed by lateral lithotomy by another surgeon. The new stone had, as usual, a large prostatic and a smaller vesical portion,



separated by a constricted neck. Near the distal end of the prostatic portion, on its inferior surface, was a facet, articulating with a perineal stone, the pouch of which communicated with a fistulous opening into the perineum. The latter weighed 2.5 grams.

532. Has had partial obstruction of urine for four months. Stone in a pouch behind the bulb. Removed by perineal incision.

533. Total obstruction for four months. Numerous and extensive perineal fistulæ. Laid open the fistulæ and found a stone as large as a pea in the membranous urethra. The third day after the operation passed an elastic catheter from meatus into bladder, packing it in the perineal wound with gauze. The fistulous opening closed, and patient regained continence of urine.

539. Impacted at scroto-penal junction. Removed by incision at that point. Wound healed well.

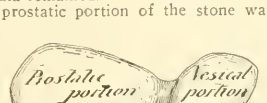
541. Perineal fistula on the right side of scroto-penal junction, through which most of the urine flows. The urethra anterior to this is of the caliber of that of a boy

of eight years, and not permeable at its proximal end. A prostatic stone can be felt by a finger in the rectum. Removed by median incision. The proximal end of the anterior portion of the urethra was then detached from its adhesions and sounds passed through to the bladder. The wound healed in eight days.

555. Prostatic stone. Was operated on in infancy by Arabic method, which left a recto-urethral fistula. This was operated on with partial success by Fuller's method of torsion of the rectum 90 per cent. toward the right.

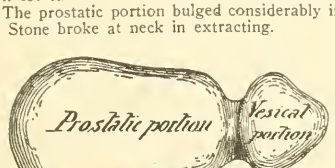
557. Had a stone in infancy, operated on by Arabic method. Two years ago was operated by median lithotomy by another surgeon, and a stone extracted from bladder. Author found a perineo-urethro-rectal fistula, with one prostatic stone in bladder. Laid all open and extracted stones. Fistula remained.

579. The prostatic portion of the stone was, as usual, the larger.



581. Has a history of passing stones by urethra. Present stone impacted in navicular fossa. Pried out. On sounding found a large stone in bladder. Patient declined operation for it.

601. The prostatic portion bulged considerably into perineum. Stone broke at neck in extracting.



606 and 607. One week before first operation had pain in right renal region, with colic and fever. Two days before operation total retention of urine. The bladder was distended above umbilicus. Stone impacted at scroto-penal junction. Broken with forceps and extracted piecemeal. The following day had again retention. A stone was detected at the same point, and extracted entire with forceps. Since then no more stones.

608. Six days ago had renal colic. Two days ago began to have obstruction, then partial retention. A small stone was pushed by Dr. Iskandar Barüdi into the bladder, but descended again, and was lodged at neck of bladder. Writer pushed it back into bladder, crushed, and removed in jaws of lithotrite.

Figures 27, 114, 98, 121, and 36 are of stones reported in previous tables of July 28, 1877, and October 30, 1880; .015 is of a stone not operated on by the author. It seems to have been moulded by lobes of prostate.

NOTES.

195. Complete continence of urine. Stone crushed with dressing forceps and extracted piecemeal.

257. Stone cylindrical, ¼ inch in diameter, extracted from right ureter.

295. Seven years before the author had done a kolpokleisis. The stone had formed in the vagino-vesical pouch. After extraction the opening was closed by three silver wire sutures. Continence of urine reestablished as before the formation of the stone.

310. After breaking up the stone, the fragments were mostly removed by forceps.

348. Stone extracted entire. Continence of urine perfectly restored.

382. Crushed with dressing f rceps and extracted piecemeal.

409. Continence perfectly restored.

415. Fragments extracted with forceps. Continence restored.

447. Fragments extracted with forceps. Continence restored.

546. Fragments extracted with forceps. Continence restored. Same case as 571 and 578.

558. Fragments extracted with forceps. Continence restored.

571. Same as 546 and 578.

578. Fragments extracted with forceps. Continence restored.

582. Same as 546 and 558. Wound tubed. Urine returned by urethra in twenty-two days.

600. Fragments extracted with forceps. Continence restored.

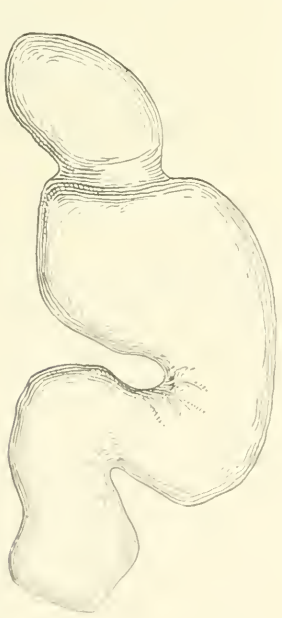
NOTES.

398. Krikor, 30. Cesarea. Had symptoms of stone in the right kidney from childhood. January 7, 1896, nephrolithotomy. An exceedingly rough stone, 2x1x1 inches removed from pelvis of kidney. There was much hemorrhage at the time of the operation, arrested by tamponing the wound. The acrid caustic urine, saturating the tampon, seemed to cause sphacelus of the substance of the kidney and of the surrounding tissues, which became gangrenous. The patient died of exhaustion the fifth day after the operation.



402 Artin. Came to hospital with symptoms of cystic kidney as large as a cocoanut. June 13, 1896, the right kidney was removed. No stone was found. The pain which the patient had felt, and for which the kidney had been removed, was not relieved. It was found to extend from the stump of the ureter to the bladder. The loin was then laid open by a vertical incision from the middle of the oblique incision, by which the kidney had been removed, downward to the crest of the ileum. The dissection was pursued retroperitoneally to the ureter, and a stone, weighing 66.50 grams and of the shape and size of the accompanying diagram, was removed. The pain was at once alleviated, but the patient, after ten hours, succumbed to the shock of the second operation following so soon after the first.

416. Two years before had an abscess in left hypochondrium, which was opened by a surgeon in his town, and a quart of fetid pus evacuated. Sinus did not heal. It was lined with epidermis for an inch in depth; stone extracted from kidney through sinus.

471. Lebibeh. Thirty-five years. Haifa. Duration one year. *Operation, Transperitoneal Nephrectomy.* The dilated kidney measures 8x6x6 inches. There were two stones, weighing together 12.5 grams. The margins of the peritoneal envelope of the kidney were sewed to the margins of the parietal peritoneum, and the edges of the wound in the wall of the abdomen brought together with several intervals for drainage strips of iodoform gauze. Patient recovered perfectly.

472. Schweir. Forty years. Duration one and a half years. Six months before October 28, 1889 the author had removed the kidney for pyonephrosis. After this operation she had symptoms of metritis, for which she was treated gynecologically. When she came again under the author's treatment she complained of a painful swelling in the right fornix of the vagina. On incising, a stone weighing twenty-five grams was removed. It had evidently been in the ureter at the time of the nephrectomy, and had worked its way down to the fornix. Patient recovered.

548. Im Taufik. Mersine. Had symptoms of stone in the ureter for three years, followed by gradual dilatation of kidney. October 2, 1902, tapped cyst and drew off 750 grams of bloody serous fluid. October 7 removed kidney from loin. Found three stones at pelvic mouth of ureter, weighing respectively 1.5, .005, and .002 grams. Patient sank, with symptoms of uremic poisoning, probably from amyloid degeneration of other kidney.

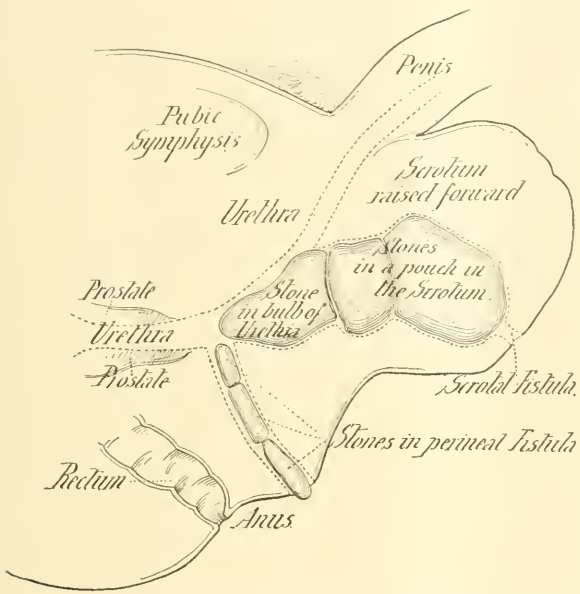
565. Adma, 28. Beirût. For three years had gradually increasing swelling of left kidney. Transperitoneal nephrectomy January 16, 1904. During operation one of the cysts burst into the peritoneal cavity. Patient died on third day from continuance of shock. Stone weighing one gram in pelvis of kidney.

586. Dhurriych, 20 years. Damascus. For several years has had symptoms of left cystic kidney. On April 19, 1905, the author made an incision four inches long half an inch below the last rib on the left side, and parallel to it, and on reaching the exterior border of the quadratus lumborum muscle, extended the incision to the pelvis of the kidney. Nine stones, weighing in the aggregate 2.5 grams, were extracted. The patient recovered from the operation, but with a lumbar fistula, through which most of the urine from the left kidney flowed. Nephrectomy advised. On the 23d of April, 1906, nephrectomy was done, the wound being packed with gauze after removal of the kidney.

Three stones were removed from sinuses in the kidney. The patient made an uneventful recovery. The wound was quite healed. Urine of normal quantity and constantly improving quality passed.

589. Presented himself with a tumor extending from the left lumbar region forward to the precordial region. It was as large as a man's head. On aspiration a straw-colored fluid was withdrawn. An incision three inches long was made in the left lumbar region, from the twelfth rib downward, just anterior to the external border of the quadratus lumborum muscle, and continued to the pelvis of the kidney. The fluid contained in the cysts drained away from this incision, which was packed with iodoform gauze. No stone was found. Several days after the nephrotomy fecal matter began to appear in the discharge and gradually increased in amount, until all the feces passed by the wound. After a fortnight the fecal matter began to be mixed with foul gangrenous shreds. A month after the operation the whole kidney with its cysts emerged as a stinking, sphacelated, macerated mass of shreddy tissue. In the pockets of this were several stones, weighing three grams. An orifice of considerable size connected the descending colon with this cavity from which the sloughy kidney had emerged. As in case 378, the acridity of the urine seems to have determined the gangrene of the kidney and the sloughing of adjacent tissues. Patient left the hospital. Result unknown—probably fatal.

VII. Scrotal and Perineal Stones.



148. Lutf Allah, 22 years, Beirut. At five years of age the patient was operated on for a large stone. During the period of contraction of the perineal wound a stone formed, and continued to the present time. A fistula existed half an inch in front of the anus, extending to the membranous portion of the urethra. This tract was occupied by a chain of three stones, the exterior of which projected from the perineal sinus, as seen in the figure. From time to time the exterior stone had been driven out, and a new one formed at the deeper part of the sinus. Many such had passed.

At the bottom of the scrotum, pointing toward its left side, was a congeries of fistulous openings, from all of which urine passed in micturition. These openings connected with a sac, containing three stones, as seen in figure, the posterior of which extended to the membranous urethra, and was faceted to the posterior perineal stone.

Operation.—The patient was placed in the lithotomy position and the scrotum laid open, the stones extracted, and the sac dissected. The perineal tract was also laid open, the stones extracted, and the fistulous tube exsected. As it was impossible to control the hemorrhage by ligatures, the cavities were packed. Subsequently their walls were approximated and healed by granulation. A small stone formed during the healing process, but was extracted, and the fistulæ then closed entirely. The weight of all the stones extracted during the first operation was 32.5 grams.

THE FUTURE OF MEDICAL JOURNALISM.*

By JAMES EVELYN PILCHER, M.D., L.H.D., U.S.A.,

CARLISLE, PA.

EDITOR OF "THE MILITARY SURGEON," THE JOURNAL OF THE ASSOCIATION OF MILITARY SURGEONS OF THE UNITED STATES.

The fourth estate in the profession of medicine is of importance equal if not superior to any of the other elements whose combination welds it into the most important factor in modern life. On the one hand, original research is at the basis of all knowledge, but of what value is original research if its results be not made known to the public? On the other hand, the intelligent practice of the art of healing is the chief object of the medical man, but how can he practise intelligently if the methods of doing so are not placed at his disposal? In the center between these extremes lies the medical press, in touch not only with these main professional factors, but with every other element small or large which contributes to professional success—in touch with all, strengthening all, supporting all, binding all into one mighty progressive whole and lending to all the qualities indispensable to success.

*The President's Annual Address at the thirty-eighth annual convention of the American Medical Editors' Association at Atlantic City, N. J., June 3, 1907.

In our own country this department of professional endeavor has attained especial development. Few realize how many physicians are engaged in medical journalism. I admit that while my own estimate of the number was high, it was not until I entered upon the duties of the important office with which this Association honored me at its last meeting that I began to gain a definite knowledge of it. And it was entirely without a full appreciation of the magnitude of the task I was assuming that I entered last year upon the work of constructing a catalogue of all the medical editors in the United States and Canada, including in my plan all participants in medical editorship, whether editors-in-chief, assistant editors, associate editors, or department editors. In order to render later indexing easy, I entered each person with his journal upon a separate slip of paper and it was wonderful how these slips multiplied, pile on pile, until finally no less than 1,150 exponents of the medical phase of the art preservative were represented, and doubtless there were still some whose names had escaped my search.

It was then among a considerable population that the American Medical Editors' Association found the field for the recruitment of its membership. There was no doubt but that every one of the

eleven hundred and fifty eligibles should be gathered into the Association and, acting upon this theory, I wrote a personal letter to each one of them, and to some of them several, inviting attention to the Association and suggesting cooperation in its objects. The correspondence involved in this campaign then was rather considerable, the formation of the catalogue itself requiring the despatching of some three hundred, and the further campaign for members among the eligibles, whose names had been listed, made necessary the preparation of over twelve hundred letters, the whole mounting up to a total of more than one thousand five hundred letters involved in one phase of the work of the president's office this year, in addition to the correspondence demanded by other features of the work.

Of some of the results of this work you have already learned from the report of the executive committee, other results in the way of increasing the efficiency, extending the authority, and widening the influence of the organization will, it is hoped, manifest themselves with the progress of time.

Much depends upon united effort. The days of sociological individualism have in all phases of human life been supplanted by aggregation. The progress from the human unit—with every man's hand against him and his own hand against the world—to the family, the tribe, the nation, and the imperial aggregation of states is the story of the growth of humanity from savagery to civilization. Collective action so long recognized in the realm of higher politics has pushed into the region of economics. The wastefulness of scattered and individual labor has become so apparent as to make consolidation the watchword of the day, even in some instances to a dangerous degree.

Collective professional study has long been an ideal of the advanced exponents of medicine, but never hitherto has it attained the importance which it has reached to-day. Association for professional advancement has irradiated into every department of the healing science, and who can deny its imperative necessity? How can the sanitarian, the gynecologist, the ophthalmologist, the general surgeon, or the military surgeon obtain the professional facility essential to scientific success without the hints, suggestions, and information to be obtained from the practice of his fellows? So essential is this that the specialist who fails to avail himself of such opportunities had better lay aside his special pretensions at once—discard his speculum, lay down his scalpel, resign his commission—for he writes himself down clearly as one who fails to read the fundamental signs which spell success. The absurd position of the aspirant to recognition as a specialist who abstains from joining with his fellow specialists in the collective development of the branch of the art, to special proficiency in which he pretends, because forsooth he "already belongs to so many societies that he cannot do justice to them," is a spectacle for gods and men! And yet a spectacle which not infrequently obtrudes itself upon the attention of the profession.

More specialized than any other medical specialty, the field of medical journalism has for nearly two score years been held together with varying degrees of firmness by the American Medical Editors' Association. Much of the time inadequate to its opportunities it has nevertheless during the passage of years been a fair reflection of prevalent sentiment as to the desirability of combined conduct. And with the crystallization of opinion and the materialization of the necessity for organized action in other directions, it has stood well abreast of the other participants in the great procession of progress. Participation in the work of the organization is to-day more necessary than ever to him who proposes to practice the specialty of medical editorship.

During the past year the Association has fixed its feet more firmly than ever before upon the rock of endurance and in the highway of usefulness. The adoption of a well considered system of government in its new constitution and by-laws has contributed to it a permanent and definite foundation. The increase of its annual dues to a fairly reasonable figure has provided an assurance of sincerity to its aspect and a promise of productivity to its soil. The publication of the handsome booklet in which the proceedings and papers of the last meeting are perpetuated gives it a definite position, a personal literature, and a manifest reason for existence.

Under the guidance and inspiration of an Association such as this the future of medical journalism insures a brilliant career for the medical journalism of the future.

The field of medical journalism is broad—wide as the lapse of the ages during which man shall be born, live out his brief day and pass into eternity. The possibilities of medical journalism are only limited by the boundaries of human endeavor. It may not be said of the medical press that

> "There is a tide in the affairs of men
> Which, taken at the flood, leads on to fortune;
> Omitted, all the voyage of their life
> Is bound in shallows and in miseries,"

but rather that there is an ever-present opportunity who loudly advertises that

> "They do me wrong who say I come no more
> When once I knock and fail to find you in,
> For every day I stand outside your door
> And bid you wake and rise and fight and win."

The prospects of medicine are brilliant. This wonderful century, with its tremendous forward strides, is but the borderland of the boundless field of medical endeavor—but the title page of the mighty book of medical knowledge whose pages posterity will turn one by one and whose teachings will not only illumine the dark spots in the medical work of the day, but furnish material in vast amounts for the greater periodicals, and even for the most highly technical publications. The professional teacher, the original investigator, the aspiring specialist, the earnest practitioner will, as before, abound in thoughts appropriate for expression in current journalism.

It has been said that man is a talking animal and if that be true the physician is a reading animal. And this is essential. For his education is never complete. Before half a score years have followed the period of his pupilage in lecture room, clinic, and laboratory, the face of his science is so transformed by the protean mutations of medicine that, without constant following of the progress of science, he would be impotent either to cope with his fellow practitioners or to meet the demands of his clientele. The medical journal is the textbook of the practitioner and this fact is the key to the most important function of the medical journalism of the future. To meet it medical periodical literature must cast aside the opportunism which has so largely characterized it in the past and become more of a creator of literature that shall be well balanced and comprehensive.

The great general medical journals already in

the field will continue to grow apace with their enormous editions and their broad fields, and judicious and intelligent management will hold them secure in the point of vantage which their precedence in establishment has insured for them.

But along with these a continual outcrop of new general journals—weeklies, bi-weeklies, monthlies, and semi-monthlies—will appear, a fortunate circumstance, for anything like monopoly of the journalistic field would savor too much of suppression to be for the good of the profession. A free course and a fair field for the journalistic aspirant whom new ideas or exceptional ability may have inspired to enter the contest for the favor of his compeers will continue to be assured by a generous, just, and high-minded profession.

With the widening of the field of medical knowledge the demand for restricted special medical journalism will increase in the future as it has during the past. The further subdivision of specialties, foreshadowed by all the auguries of the age, will necessitate additional exponents for each new phase of medical science, culminating in an extension of special journalistic work as noteworthy as it will be encouraging. Each new discovery will have its special spokesman and, as the number of practitioners grows, they will increase in number as well as in circulation.

It is hardly to be supposed too that new medical sects will fail to arise hereafter as hitherto and with each of these a new crop of medical journals will spring up.

There will continue to be a field also for the weaker grade of journals whose function is to provide an outlet for the energy of the ambitious young man both in the editorial and the authorial capacity. Men will continue to write *for* practice as well as *from* practice. Nor can we expect that this class of publications will improve to any great extent in character, although they may well have a fuller table of contents.

The greater the number of journals then with their voracious call for pabulum to nourish the mental appetites of their readers, the greater will be the productivity of the profession. The quantity of medical literature published is enormous, but the amount which never escapes from the trammels of the author's manuscript is perhaps still greater—certainly equally great. At a meeting of a medical society with a membership in two States, of which I am a member and which holds regular annual meetings, there were presented last year ten set papers and fifteen clinical reports, not one of which has been offered for publication in a medical journal. In the medical society of my county, which meets quarterly, about a dozen papers are presented each year, and some of them followed with active and interesting discussions, and I recall but one of the papers which has emerged into the light of publicity through medical journalism. I can hardly conceive of a very different situation prevailing in other parts of the country. So that it is evident that there is an abundance of material available for publication, much of it not in suitable shape for the printer it is true, but all of it nevertheless available for the pruning, shaping, and revising hand of the editor. But little of this material is without value. Occasionally it is true a paper is but a rehash of or possibly a wholesale steal from a textbook or a journal, but more frequently they represent the opinions and practice of the average physician, whose work does not get beyond the audience of his society or neighborhood. This is often due to modesty on the part of the author, frequently it arises from a lack of knowledge of the mechanics of literary construction, and in many instances it is because of the busy life with its absorbing cares which prevents the final preparation for publication. It is evident then that the journalism of the future, judging by the criterion of the present, need not lack for material upon which to feed its public.

I differ quite fundamentally from many of my colleagues upon the question of restricting the work of many more or less inefficient contributors to medical periodical literature. I favor the writer who makes one case the text upon which to found a discussion of the literature of an affection. The study which he has devoted to the preparation of his paper cannot but be of advantage to him, and, if perchance the publicity which it gives to its author should bring to him other cases in consultation and otherwise, the resulting intelligent experience will enable him to produce still more and possibly more original material upon his subject.

On the other hand the readers of the paper cannot fail to derive some benefit from the effort—whether it be from the consideration alone of the case upon which it is founded or from the review of the literature with which it is accompanied. Few men are so erudite that they cannot be benefited by a refreshment of memory. Man is so frail that it is a never-ending "line upon line and precept upon precept" by which the mental machinery must be kept constantly rubbed up and polished or the rust of forgetfulness and intellectual lethargy will clog his practice and obscure his judgment. The personal touch of acquaintance with the author, perhaps even the habit of referring to familiar pages, may incite the perusal of a paper—whatever be the cause, the act cannot but reflect beneficially upon the reader even though it accomplish nothing but the extraction of forgotten facts, theories, or methods from his own subconsciousness.

But the medical journalism of the future will be characterized particularly by certain outgrowths of the present situation, each a development of existent conditions, an elaboration of contemporary circumstances. The evolution will occur along lines resulting in the production of two ideals of medical journalism—the recorders and the creators—both of the greatest necessity and both of the highest value.

To the former class will pertain the majority of the association and society journals which have already attained so high a degree of efficiency and whose important function will chiefly be to record the work of the members of the organizations for which they are mouthpieces and thereby to inspire them to renewed and combined activity along the lines of their profession. No man can foresee the tremendous consequences that may arise from the influence of this factor in medical journalism in unifying the profession, stimulating thought, and extending the influence and authority of the medical man in the community.

The other chief factor in the medical journalism of the future may be the product either of a private publisher or a public endowment—in any case it must have no obligation to publish any material that may be submitted to it by agreement with medical societies or individuals. Its editor will be autocratic in his action upon all matters published in its pages. It will contain few voluntary contributions, for its space will be largely taken up by well proportioned studies undertaken at the suggestion of the management by experts selected

for the purpose. Its editor will have at his disposal funds for commanding original research by members of his staff. He will have assistants in every department of medicine whose duty it will be to keep a careful lookout for new theories, original discoveries, and promising advances in the art of healing and the allied sciences. He will be able to attach to his journal writers of facile expression, authors of attractive diction, students of untrammeled originality, and observers of unvarying accuracy. He will furnish to his readers the complete facts concerning every advance in medicine and avoid the loose threads and unconcluded topics which are so common in the general press. His journal will never be an organ for the exploitation of any special line of thought, any medical fad, feature, or sect, but it will be catholic in its views, comprehensive, and conclusive in its text, well balanced and well proportioned in its contents, a leader and guide to the practitioner, an inspiration and stimulant to the student, and an instrument of real value to the world.

Is this an ideal? It may be so, but it is an ideal that may readily be transmuted into a reality, a reality which the future medical journalist will beyond peradventure behold.

The medical journalism of the future then, with these two great divisions and the numerous intermediate phases in which it will appear, will not fail to be an advance upon that of to-day, an advance along all lines, an advance significant not only of a progressive profession, but an advance inspired by a fuller appreciation of the duties, responsibilities, and opportunities of the medical editor. In this the American Medical Editors' Association will be a governing and guiding factor. Its face will always be set toward higher and better things and its attitude will be characterized by the glorious persistence which marked the conduct of the famous Genoese mariner, when

> Behind him lay the gray Azores,
> Behind the gates of Hercules;
> Before him not the ghost of shores,
> Before him only shoreless seas.
> The good mate said: "Now must we pray,
> For lo! the very stars are gone.
> Brave Admiral, speak—what shall I say?"
> "Why, say, 'sail on, sail on, and on.'"
>
> "My men grow mutinous day by day;
> My men grow ghastly, wan, and weak."
> The stout mate thought of home; a spray
> Of salt wave washed his swarthy cheek.
> "What shall I say, brave Admiral, say,
> If naught we sight but seas at dawn?"
> "Why you shall say at break of day,
> 'Sail on, sail on, sail on and on.'"

And so shall we, too, in the high vocation of cultivating and perpetuating the knowledge which shall diminish suffering, alleviate pain, and lengthen life press on and on and on. The future of medical journalism will continue to brighten and its activities never cease to expand throughout the ages during all of which it shall ever crown the mighty archway of medical practice as the great keystone of knowledge which shall time without end unite theory with application and learning with practice in the ever glorious aims of deferring disease, delaying death, and maintaining health.

Uterine Cancer.—One-half pint daily of a strong decoction of powdered Ceylon cinnamon will limit hemorrhage from uterine cancer, and is claimed to reduce the fetor of the discharges.—*Medical Council.*

SYPHILITIC TUMORS OF THE BREAST.*

By JOSEPH B. BISSELL, M.D.,

NEW YORK,

SURGEON TO BELLEVUE HOSPITAL AND ST. VINCENT'S HOSPITAL.

The breast is a not infrequent location for the early specific lesions. The primary sore, mucous patches, condylomata, and the early eruptions, often occur upon the nipple and its neighborhood. These common symptoms require, as a rule, long and tedious description, which the syphilographers delight in, but which are of no special surgical interest to us. For the purpose of this brief paper it is enough to consider the late manifestations, the gummatous form of the infection. It appears in two varieties, either as one or more large circumscribed tumors, or as an infiltration, somewhat extensive, dense, usually deep seated in its origin, and most interesting to us from the standpoint of treatment.

Proper treatment of any disease or abnormal physical condition can come only from correct diagnosis, and a thorough understanding of the affection to be treated. Most particularly does this hold true in tumors of the breast.

An amputation of this part, even to the extensive details of the Halstead or Willy Meyer methods, can be easily done, though at times it may be prolonged and tedious. But it means at best mutilation and a certain amount of risk to the patient. Moreover, in the more youthful cases, those which occur before the climacteric, such an operation produces a certain mental and physical effect upon the human body, more especially if it be that of a woman, which unfits her for certain functions in life. Whether this disturbance is due to the altered internal secretions, or to the shock which such an extensive procedure causes, or to both, is still undetermined, but it is present and should be considered in making up the surgical verdict. Lopping off half of the anterior surface of the breast, or in some cases both breasts, down to the ribs, and dissecting out the axilla, besides being an artistic and physical desecration, has a psychical and moral side to it which should cause us to consider carefully all the possibilities before deciding upon operating.

In malignant growths the longer one waits before removing them, the greater the chances of their early return. When the indications are definite and clear there should be no hesitancy in doing an immediate and complete operation. But just because we have the skill and the tools with which to do this work, it does not follow that we should always be using these tools. It is much easier to cut than to cure without cutting, especially if the diagnosis has been hastily and crudely made. Hence this plea for a thorough examination, ample deliberation, and, if possible, a more exact diagnosis.

The text-books on surgery almost without exception give very little attention to gumma of the breast. Von Bergmann dismisses the subject with the curt statement that "it is extremely rare." Keen, in his newest publication, says the diagnosis may be quite impossible, excepting for the treatment. Most of the text-books ignore the condition. Recently a number of cases have been reported; the writer has had at least six in which the diagnosis was made and treatment followed by recovery confirmed it.

Gummata of the breast are to be differentiated from cysts in the organ, from tuberculous disease of the breast, and from malignancy. Other tumors of this

*Read at the meeting of the Hospital Graduates Club, March 28, 1907.

region are, as a rule, easily eliminated in the diagnosis. Cysts, or chronic cystic mastitis, consist of individual nodules or cysts in the breast substance, which fluctuate and are not adherent; there is no reddening of the skin when uncomplicated; the nipples, if retracted, are only slightly so. Frequently fluid can be squeezed out of the nipple. The number of fluctuating insensitive tumors, the smooth breast surface with the sensation of a bag of marbles at times, together with absence of glandular enlargement in the axilla, determine the diagnosis.

Tuberculosis of the breast is characterized by an inflammation of the breast gland, which varies from a circumscribed cold abscess to a disseminated nodular infiltration, much resembling multiple carcinomatous nodules. Sooner or later these inflammatory foci become confluent and break down, opening at various points of the thin and translucent skin. The nipple is retracted and the breast irregularly softened and hardened in spots. The axillary glands are thickened and often broken down. This condition may continue a long time without great local or constitutional changes. The disease in this location is not common: it is usually found in women, is generally easy of diagnosis, and is not likely to be confused with gumma of this region. Frequently tuberculosis of other organs is present. The diagnosis in the later stage is not difficult, and can be determined beyond question by means of the microscope or by guinea pig inoculation.

If, as is rarely the case, the disease is primarily in the breast, the treatment indicated is like that for malignancy, complete removal of the disease by the knife. The diagnosis between gumma and cancer of the breast varies from those cases where the symptoms differentiate the two diseases quickly and surely and with ease, to the cases in which this differentiation is almost impossible. The necessity of making such a diagnosis is obvious, for it is essential to the best treatment and in order to obtain good results, to avoid uncalled-for mutilation and destruction of parts of the body as well as injury to the mind.

Syphilitic symptoms elsewhere, the history of earlier lesions, a knowledge of the disease at any time in the marital partner, should create more than suspicion. The fact that a lumpy swelling has occurred before in one or both breasts and disappeared with or without treatment points toward a specific infection. These gummatous tumors develop slowly and painlessly, and they ulcerate and discharge much earlier than cancerous nodules break down. They are free nodules early in their course. Often after breaking down they discharge a thick, sticky fluid, and they leave a cicatrix on healing. They begin probably in muscular or fibrous tissue. The nipple as a rule is not retracted, and when it is differs from the typical retracted nipple of malignant disease. The new growth in cancer is more dense than in gumma, which occurs as a rule earlier in life than carcinoma. The lymph glands were found enlarged in some of my cases and not in others. Those in the axillary space are not to be made out as a rule in specific disease.

The glandular enlargements are hard, sharply rounded, and entirely painless in cancer. In syphilis, if present, they are not so hard, and are more irregular and broad or thick in shape. Where the deposits in the breast have been present a considerable time and there are no axillary glands involved, the diagnosis favors syphilis.

Cancer is almost always in the outer upper or lower quadrant. Gumma may occur in any part of the gland, but it originates as frequently in one position as another.

The main test in differential diagnosis is, after all, that of treatment. This is always available, and now that a modern mode of treatment allows of a quick determination it is the most valuable diagnostic help.

In the hypodermic administration of mercury we have a method which demonstrates rapidly, safely, and surely the presence or absence of syphilis. With this means available it is fair to assert that for the most part little difficulty should stand in the way of a differential diagnosis. The hypodermatic injection of a mercurial salt can be pushed quite rapidly if necessary. If time presses, in such a case injections of a soluble salt may be given every day for a number of times. Recently a patient at the hospital under my care was given two injections a day for thirty days, with no objectionable symptoms from the use of the drug, and with great benefit to his serious syphilitic invasion. The following cases illustrate the subject:

Case I.—A woman, married, thirty-two years old. January 17, 1898. Has had a "lump" in her right breast for nearly a year. A few months ago she noticed a similar condition in the left. At first there was no pain, but later at times there was sharp pain, always at night. Examination made on the date of first visit showed a tumor, irregular and flat in shape, not tender to the touch, involving the inner half of the right breast and extending in a hooked-shaped process outside and below the breast gland into the pectoral muscles. The left breast was in a similar condition, but less marked. The right nipple was retracted to one side, no enlargement of the axillary lymph glands could be discovered, but the epitrochlear glands were typical, as were also those of the cervical region. A history of repeated attacks of sore throat, of mucous patches, falling of the hair, and a scaling eruption made the diagnosis positive. The rapid melting away of the tumors under heavy doses of mixed treatment proved a satisfactory sequel. Within three months the patient had lost all of the abnormal growth, and I heard from her a few years ago, saying she was free from any symptoms of syphilis, and that her health was apparently normal.

Case II.—Mrs. J. C. H., forty-eight years old. December 28, 1903. Presented herself at the hospital for operation for cancer of the breast. She had in her right breast, situated in the lower inner quadrant, an irregular indurated tumor, flat, the size of a lemon, fluctuating at several points. It had been present nearly a year, increasing very slowly until in the past six months, when fluctuation appeared, and it had developed rapidly. The patient gave a typical history of syphilis. She was put on antisyphilitic treatment and the tumor disappeared slowly. In June, 1904, there was no evidence of any trouble in the breast.

Case III.—A woman of middle age, with an indurated growth in the right breast, outer lower quadrant, was operated on by a colleague of mine at the suggestion of his house surgeon. Soon after beginning the operation he became suspicious of the diagnosis and an incision into the tumor showed characteristic structure of gumma. He did not remove the breast and under appropriate treatment a cure was effected.

Case IV.—Mrs. R., thirty-nine years old. November 3, 1906. The patient was seen in consultation for a growth in the right breast, outer side. It did not involve the skin, but went deeper than the

breast gland; nipple retracted toward the outer circumference, no enlargement of lymph nodes, no pain, very slow growth. The patient gives a history of syphilis several years ago. Hypodermic injections of 1-4 gr. of arseniosalicylate of mercury, together with the iodide of potassium which she had been taking for some months previous to my seeing her, produced a distinctly beneficial effect, lessening the size and tension of the growth decidedly. And on her second visit, February 8, 1907, a note was made that the tumor had decreased in size perceptibly in the last three months, but, becoming impatient, she lost her temper because I could not promise an immediate cure by operation, without deformity to the breast, and deserted me for another surgeon, who informed her he thought the diagnosis was probably syphilis. I have no doubt that this was a late syphilitic lesion, curable by suitable treatment, although the possibility of a coincident malignancy is possible.

Case V.—January 25, 1905. Mrs. R. H., thirty-five years old, whose husband had been under my care for syphilis some years before. She had never had any evidences of infection, but about two months before this date she had noticed a lump in the left breast, which had gradually increased, without pain. It is now the size of a small egg, flattened out and irregularly ridged, with a retraction of the nipple toward the greater prominence of the tumor, which is situated in the lower half of the breast. Epitrochlear and cervical lymph nodes were made out, but none in the axilla. She was given hypodermics of arseniosalicylate of mercury, 1-4 gr., every third day, till the tumor began to disappear, then less often for several weeks, at the end of which time it had entirely gone, leaving the breast apparently normal.

From the experiences of my own and those of others I would draw the following conclusions:

1.—That gummata of the breast are not as rare as the authorities would lead us to infer.

2.—That as a rule these late syphilitic lesions of the breast can be quite easily differentiated by careful diagnosis.

3.—That to a certainty some breasts can be saved from operative procedures, which heretofore have been needlessly sacrificed.

4.—That in case of doubt an effort should first be made by means of this quick method of treatment to exclude absolutely the possibility of the tumor being syphilitic.

46 West Fifty-fifth Street

THE PREVENTION OF VENEREAL DISEASE.*

By A. H. BAKER, M.D.

Elmira, N. Y.

So much has been said and written concerning the prevention and treatment of the many manifestations of tuberculosis it has gradually overshadowed all other medical subjects in the medical and lay mind. There is, however, another subject of just as vital importance to the individual and to the public which is slowly receiving the attention it deserves and regarding which the public is slowly becoming educated, and on this subject I wish to speak to-night. It is the better education of the public regarding the immediate and remote effects of venereal diseases.

*Address of the retiring president delivered before the Elmira Academy of Medicine, January 2, 1907.

It was my privilege, during my recent stay in New York, to listen to a symposium by members of the Academy of Medicine and some invited guests on this subject, and I then determined to bring it before our Society at the first convenient opportunity. The men who contributed to the symposium were Drs. Bovée and Johnson of Washington, Marrow, Grandin, Goffe, and Jacobi of New York; and other men, notably Dr. John A. Wyeth, entered heartily into the subject and gave to it their best thought and attention. I mention this because I think it affords a suitable explanation of why we may think and write on this subject, and I only regret that I am unable to bring the power of thought and argument to bear upon it it so richly deserves.

The victims of tuberculosis are, to a notable degree, the weaklings of society, and, when looked upon without sentiment or sympathy, perhaps wisely removed by an unchangeable natural law; on the other hand, victims of social diseases are, in most instances, healthy and well developed, and physically best endowed to propagate a healthful race of men and women.

Of the two diseases, gonorrhea and syphilis, I think it is now conceded by most observers that the injurious effects, immediate and remote, on the person suffering with the disease, are greater from gonorrhea; while the evil results to the offspring are greater from syphilis. Dr. Prince A. Morrow in his work entitled "Social Diseases and Marriage," says the influence of syphilis upon the offspring is expressed in one word, "polymortality." In this paper where figures and statistics are given they are largely taken from Dr. Morrow's book, supplemented by some jotted down at the medical meeting referred to above. Seventy-five per cent. or more of the male population suffer at some period from gonorrhea, and from 5 to 18 per cent. from syphilis. Opinions vary somewhat as to the percentage of cures in these diseases. In gonorrhea a conservative estimate places the uncured at 33 1-3 per cent. in both men and women. When the disease passes the internal os and attacks the endometrium, tubes, and ovaries, practically no woman recovers. In syphilis the percentage of uncured is much greater, but the virulence of syphilis seems to diminish as time goes on so that succeeding offspring show less and less its blighting effects. Gonorrhea, on the other hand, no matter of what age or attenuation, when planted in virgin soil, develops its most active and baneful consequences. I do not wish to be understood as claiming that all women who marry men who are not cured will be ruined, or that all children born of mothers who have gonorrhea will become blind; nevertheless many such women will be ruined and many such children will be made blind.

Another fact, brought out by Dr. Jacobi, is that the little children of infected parents often contract gonorrhea of the genital tract resulting, in little girls, in endometritis which produces in later life sterility; and causing, in both little boys and little girls, pyelitis and fatal kidney complications. Every practitioner who has observed the abdominal surgical work necessary in women, cannot have failed to note that a very high percentage, variously estimated at from seventy-five to ninety, is directly traceable to gonorrheal infection. And, as in nearly all other diseases, the higher the intellectual and social position of the patient the less the resisting power and the more far-reaching and destructive the disease.

And when the sum of the knowledge of these statistics is placed before us, what is the lesson it teaches? To my mind it is this: Educate the young men and young women, arouse in practitioners a livelier sense of their responsibilities and a desire in them to treat more conscientiously and follow up more diligently their cases of venereal diseases until they know a cure has been obtained. When I say educate the young men and young women I do not mean to proclaim a subject so unclean from every housetop, but at every proper time and opportunity it should be brought before them with all the force of argument of which we are capable. One of the most reprehensible practices of which medical men in the past have been guilty is the minimizing of the immediate and remote effects of venereal diseases. Imagine, if you can, a more undesirable position than that of a medical man when called to attend a young woman, infected in her early married relations, and he makes the audible diagnosis of violence, cold, wet feet, or any one of the many explanations which satisfy the laity, while in his heart he knows she is but an added victim of man's ignorance or viciousness. Morrow says: "She is an 'innocent' in every sense of the word—she is incapable of foreseeing, powerless to prevent this injury. She often pays with her life for her blind confidence in the man who ignorantly or carelessly passes over to her a disease he has received from a prostitute. Such misfortunes do not befall alone the vicious and abandoned women who indulge in licentiousness and irregular living. The victims are for the most part young and virtuous women, the idolized daughters, the very flower of womankind. They are the women endowed by nature with all those physical attributes of health and vigor which fit them to become the mothers of the race."

At every convenient opportunity I deem it to be the duty of every physician to explain carefully to the young men who come to him professionally the dangers and far-reaching consequences of venereal diseases, their incurability, and that the baneful influence of gonorrhea and syphilis may become manifest twenty years after the primary infection. How much more accurate the knowledge thus obtained than that acquired from evil youthful companions or more evil men, usually the only source of information! A clear knowledge of the sequelæ of gonorrhea, such as urethral stricture, seminal vesiculitis, and diseases of the prostate, bladder, and kidneys; and of paresis, locomotor ataxia, blindness, etc., from syphilis, would have a restraining influence on a large number of young men, and especially those whose mental and physical attributes make them worth saving. The various means for preventing infection at the time of exposure are becoming very popular at present, but to me they seem of doubtful morality and to encourage unclean living.

Young men should be taught that a continent life is not detrimental to health, and to avoid the unclean woman as they would pestilence or plague. Warn them against the danger of an illicit intercourse after they have become engaged to marry. How many of us have had cases of venereal disease to treat in men, contracted after the date of their marriage was set and there was insufficient time under any circumstances for them to recover? Also explain to them that the fathers and mothers of marriageable daughters will be taught that when a previously healthy girl develops a cystitis or pelvic inflammation immediately or shortly after marriage there is usually but one reason for it and that reason is the presence of venereal disease in the young husband.

Advocate early marriages. If there is one thing more than another medical men should set their faces against it is the demand of society that a man shall be able to furnish every luxury and comfort in a home before he marries. It simply means he will finally come to the marriage covenant unfitted either in years or health or both to give to society that which could be justly expected of him. Arouse and instill in the minds of young women the exalted position of a mother over that of the social, childless butterfly.

If this advice be given, if this duty be faithfully performed I have the profound faith and confidence in the young men of our land who are becoming so interested in athletics, in education, in clean, wholesome living, that once the path is pointed out to them the majority of them will follow it, and bring to the nuptial couch the same degree of purity in themselves they so jealously demand of the one who is to share with them life's burdens.

CHRONIC PERFORATING ULCER OF THE BLADDER.

By HENRY K. LEAKE, A.M., M.D.,

DALLAS, TEXAS.

In the *Journal of the American Medical Association* of March 23, 1907, Dr. G. Walker gives a report of two personal observations of patients asserted to have simple ulcer of the bladder. He describes two types of the disease—acute and chronic—and states that the symptomatology closely simulates that of cystitis, from which it can be differentiated only by cystoscopic examination.

Many years ago, in an article which I published on this subject, I said that in English literature Lawson Tait was the first to call the attention of the profession to this rare affection of the diseases of women, and that he had given the credit to Rokitansky for having preceded him in describing it. Writing to the *Lancet* for March, 1871, Tait gave the brief histories of four cases of chronic perforating ulcer of the bladder of which he had personal knowledge. Two of these cases he treated in association with his great master—Sir James Y. Simpson. The third case was in his individual practice and he was present at the post-mortem examination of a fourth case which, he says, put him in a position to prove the views of Rokitansky, the well-known distinguished pathologist.

On analysis of Tait's article it is evident that in the first three cases he may have made an error in diagnosis, for the symptoms were not different from those of ordinary cystitis—a disease not infrequent in women—and as cystoscopy was then in an inchoate stage, no inspection of the bladder was undertaken. In the fourth case, I assume that no diagnosis was made previously to the death of the patient, after which the post-mortem discovered "a limited perforating ulcer," presumably situated at the neck of the bladder, for Tait says the perforating ulcer most frequently seems to exist at this point.

Tait had a double purpose in sending his communication to the *Lancet:* First, he eulogizes his revered teacher, Sir James Y. Simpson, for having originated the operation of vesicovaginal fistula to cure chronic perforating ulcer of the bladder; and,

second, to warn the profession of the existence of a rare disease in women which, imitating cystitis in its clinical history, might deceive the physician who, relying upon the ordinary means for treating cystitis, might delay or neglect the adoption of surgical measures, by which alone the successful treatment of what Tait calls this "terrible disease." may be accomplished.

That, exceptionally, it may be, a perforating ulcer may exist in the bladder remote from its neck, I had occasion to show in the article above referred to, wherein I narrated the history of a very interesting and instructive case that had occurred in Dallas several years after the publication of Tait's article.

The wife of a prominent and greatly esteemed physician, recently deceased, a middle-aged and nervous woman but otherwise in the very best health, was taken with symptoms ordinarily attending inflammation of the bladder. Her condition growing gradually worse, several physicians were called in to the case. One of these urgently advised, and ultimately made forcible dilatation of the urethra, the patient being anesthetized. The operation was followed by an aggravation of all the symptoms, which became progressively intensified to such a degree as to render the condition of the patient most pitiable. For weeks she suffered the greatest agony, except when under the influence of powerful opiates, which added their baneful effects to those of the original disorder. She was transferred to New York and placed under the care of a gynecologist of world-wide fame. From reports received I understood that this gynecologist was puzzled as to the exact nature of the case, but treated it on the hypothesis that the symptoms were owing to a severe form of cystitis, although he refrained from making a vesicovaginal fistula which had been recommended by Emmet in the treatment of such cases. The patient remained in New York several months without the slightest benefit from her visit, her condition from day to day becoming more serious. Finally she returned to Dallas and I was called to attend her. From a woman of good physique and lively temperament I found her emaciated, neurasthenic, and melancholy. With a view of at least giving rest to the bladder from its frequent and painful contractions, I made a free vesicovaginal fistula and as suggested by Emmet, introduced a drainage button to keep the incision open. This procedure gave much immediate relief, but did not entirely remove the pain, which soon began and continued above the bladder. After weeks of constant suffering and exhaustion, death occurred, the patient retaining her mental faculties to the very last. A post-mortem examination disclosed a uniformly round ulcer in the region of the fundus of the bladder above the trigone, which had perforated all the coats. The edge of the ulcer was clean cut without undermining and with little if any thickening in the outlying tissue. There did not appear to be much cystitis, nor was there apparently any change of structure in the vicinity of the neck of the bladder, a fact remarkable considering the characteristic tenesmus which always had been a prominent feature of the case. However, a more careful perhaps microscopical, examination of the parts might have shown substantial alteration. There was marked pelvic peritonitis, in excess overlying and radiating from the base of the ulcer; there were no sloughs in the cavity of the ulcer which seemed to have formed gradually by molecular disintegration, and the mucosa appeared to be of normal character almost to its circumferential edge; in short the ulcerating cavity seemed as though just recently punched out except over its very base, where a large amount of peritoneal infiltrate had occurred.

I have seen the more or less chronic perforating ulcer at points in the intestinal tract, several times in the duodenum, and I have operated on patients with gangrenous perforating ulcer of the appendix which was neither inflammatory, tuberculous nor typhoidal—a disease which recently by English surgeons, from its course and pathology, has been separated from the ordinary forms of appendicitis. In all these examples I am impressed with a similarity in appearance of the ulceration, the same fundamental cause being common possibly to the entire class although, of course, this view may be questioned. On account of the oftentimes insidious origin and progress leading to fatal termination, these ulcers are of great interest to the physician and surgeon. Particularly would I cite the gangrenous perforating ulcer of the appendix just mentioned, for here death may ensue upon a fatal perforation of the organ which had been preceded by little or no symptoms to indicate the disease, and this is what might be expected in such cases. Much depends upon the location of an ulcer in the body of the appendix and whether or not inflammation has radiated towards the base of the organ and involved the peritoneal attachment, for a large portion of the appendix is devoid of sensory nerves and thus may be involved in disease without giving rise to pain, either objective or subjective. The gangrenous perforating ulcer of the appendix referred to is seldom, if ever, attended by inflammation and therefore may perforate unrestrained by contiguous peritonitis, a feature so conspicuous in the case of the perforating ulcer of the bladder described above. Should the ulcer be situated near the base of the appendix, definite symptoms may exist that will direct attention to disease which may exist at this point.

Mr. Tait did not venture upon an explanation of the pathological cause of these perforating ulcers of the bladder; he simply stated that he endorsed the views of Rokitansky which, unfortunately, he omitted to give in his article. The explanation put forward by Dr. Walker is a generalization too narrow to enlighten us as to the real cause of this malady. He says it is "due probably to local disturbance in, or complete blocking of the terminal, or by an interference with the trophic nerves." The nervous and circulatory systems provide for the nutritional activity of every part and which, being affected by the primal cause, act as secondary factors in the beginning and progress of most morbid processes. This is now known to be true in the case of gastric ulcer which formerly was thought to be caused directly by a localized thrombosis or embolism, but the primal cause has to do with defective cell metabolism, the origin and nature of which we do not quite understand; it may be that the environing blood plasma of the cells supplies the disturbing agency which initiates their destruction.

Although the anatomical constituents of the hollow viscera are somewhat different—for example the variety of glandular tissue—nevertheless an argument may be drawn from this fact—that a common cause lies at the root of these perforating ulcers, so much alike in appearance, history, and termination, and that this cause is abnormal cell metabolism which in some mysterious way has been set up in a particular part of the organism, and brings in its train secondary factors which further contribute to the deranged function and finally to the utter destruction of tissue areas involved in the process.

REPORT OF A POSTOPERATIVE CASE OF FIBROID SARCOMA UNDER THE ENZYME TREATMENT.

By WILLIAM T. DORAN, M.D.,

NEW YORK.

Mrs. U., age 27, native of the United States. Family history, negative. Personal history, she had the usual diseases of childhood, but was otherwise well until July, 1906, when she noticed increased length of menstrual period, increased menstrual pain, and sallow color of face, which she attributed to liver trouble.

This continued until the following December, when the family physician was consulted on account of menorrhagia. Dr. J. C. Taylor, to whom the patient was referred, advised an immediate operation. He placed her in the New York Polyclinic Hospital, and on December 21 operated, assisted by the writer. A panhysterectomy was done and the involved glands removed so far as was possible (the obturator glands were involved at this time). The specimen was examined by Dr. Jefferies of the New York Polyclinic Laboratory, and a positive report of fibrosarcoma was made.

Recovery from immediate effects of the operation was uneventful, but within the second week following the inguinal glands on right side became involved. Later on there was involvement of the glands on the left side. Upon bimanual examination continued enlargement of the obturator glands was found. There was marked induration of all the involved glands, but no evidence of inflammatory conditions. Enzyme treatment was suggested; nothing was promised at the time from its use, save a possible nutritional gain. After conference with Dr. Margaret Cleaves, the enzyme treatment was instituted on January 7, 1907. At this time the patient weighed 115 pounds and was weak and anemic. On the first day five minims of trypsin (special strength) was given hypodermically. This was gradually increased each day until on the fourth day twenty minims of trypsin was administered. At this time the use of amylopsin was begun and injections of twenty minims of trypsin and amylopsin were given daily. The doses were gradually increased until February 9, when the patient left the hospital, at which time she was receiving thirty minims of each daily. Up to this time there had been only slight rise in temperature (1.5°) and an increased pulse rate. Treatment was continued at home every other day, forty minims of both ferments being used. In the beginning of the third month of treatment there was marked tenderness in both breasts, particularly in the left one, which was accompanied by a dragging sensation. Examination revealed no enlargement: coincidentally the patient suffered from nausea and headache. These symptoms I ascribed to the treatment. The dose was gradually increased until sixty minims of each was given every other day. The glands gradually diminished in size and the patient increased in weight and strength. Since April 10 the patient has been treated twice a week only, the maximum dose of sixty minims each of trypsin and amylopsin being given.

During the treatment the patient has taken internally, holadin, twelve grains daily; pancro hepatic (extractum pancreatis, three grains; inspissated oxgall, one grain) daily. Extra diet was encouraged, iron tonics used for blood. The patient was examined weekly by Dr. Taylor. The glands gradually diminished until a very slight enlargement of one inguinal gland on the right side only is to be noticed at date of writing.

To-day the patient expresses herself as feeling entirely well, takes very long walks without tiring, has good color, and weighs 137 pounds, a net gain of twenty-two pounds since commencement of treatment.

This patient has never had hypodermic abscess.

129 East Fortieth Street.

A New Method of Shoulder Joint Excision.—At a recent meeting of the London Clinical Society Mr. T. H. Kellock presented a paper on this subject. He noted that in excision at the hip the section of bone was made within the capsule, and no muscular attachments to the femur were disturbed. In excision at the shoulder the humerus was divided through the surgical neck, insertions of important muscles into the tuberosities were sacrificed as well as, in a child, the most important seat of growth of the humerus. The operation described was an endeavor to save these muscles, and the epiphyseal line while preserving a movable joint; it was carried out by removing the necessary amount of bone from the scapular instead of the humeral side of the joint. After opening the joint by a long anterior incision, the muscles attached to the upper end of the humerus were retracted, the coracoid process was broken, but not completely separated, and turned a little downwards with the origins of the biceps and coracobrachialis muscles. The neck of the scapula was sawn through and the glenoid cavity completely removed, sacrificing only the long tendon of the biceps and a part of the middle head of the triceps, structures of comparatively little importance. The operation had been performed on a man, aged forty-one, who had sustained dislocation of the left shoulder complicated by fracture at the surgical neck of the humerus eleven weeks previously. The fracture had united firmly in good position, but the subcoracoid dislocation remained unreduced. Passive movements were commenced early. The result had been fairly satisfactory; flexion and extension were quite good, abduction fair, but rotation of the humerus on its own axis poor, but all these movements were improved by exercise and rubbing. Another time it might be advisable to add a posterior incision and divide the neck of the scapula from behind.—*British Medical Journal.*

An Appreciation of Hunter.—In a recent Hunterian lecture Mr. Henry T. Butlin spoke as follows: "There is no machine with which to measure greatness; and if there were one it would have to be made in many different forms. For the qualities and actions which go to make up the greatness of one man would so ill befit another, equally great in his own particular sphere, that the same mould could not be applied to both. There is, however, one test which is generally accepted as evidence of a great mind, whether it be the mind of a ruler, of a philosopher, of a poet, or of a man of science. It is that 'deep things should be discovered to him out of darkness'; in other words, that he should see clearly truths which are still hidden to ordinary mortals. And on this test I venture to class Hunter as one of the greatest men that ever entered our profession. Not for the museum which he made, or for his discoveries in physiology and comparative anatomy, or for the wondrous example of industry and determination which he has bequeathed to us, and certainly not for the improvements which he actually introduced into the practise of surgery, although any of these things would have entitled him to a high place in our esteem, and all of them together would have placed him very high indeed, but because the true relation of surgery to science was revealed to him nearly 100 years before it was so clearly recognized by those who followed him that they were forced to act upon it."—*Lancet.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, July 6, 1907.

DIET AND STERILITY.

IT is the fashion in these days to attribute many of the ills of modern life to injudicious eating. The great consumption of flesh meat especially is blamed for a larger proportion of the noninfectious maladies which plague civilized man. Gout, rheumatism, cancer, arteriosclerosis and kidney disease, epilepsy, some forms of insanity, and the protean manifestations of autointoxication are among the more serious of the evils which are attributed to an indulgence, or at least an overindulgence, in meat. To this list Dr. Malcolm Campbell of Edinburgh would add, tentatively, a diminution in the birth-rate. It occurred to this investigator that the alarming and persistent decline in the birth-rate might be due in part to uterine changes induced by an unphysiological diet, and he accordingly undertook a series of experiments to determine this point. The account of his investigation is given in the *British Medical Journal* of May 25, 1907.

The animals employed in the research were female rats. The uteri of eighty-six animals were examined both macroscopically and microscopically, the tissue for examination removed being from the same area, the junction of the distal and mid thirds of the uterus. Eight wild rats, in various stages of development, from the immature to the adult animal, were examined in order to form an opinion as to the structure of the uterus in animals living, presumably, under natural conditions. The remaining animals were divided into five series, namely: (*a*) Thirteen animals fed, from weaning, for periods of from nine to fourteen weeks on an exclusively milk diet; (*b*) twenty-seven animals fed for periods of from twenty-one days to nine months on bread soaked in milk; (*c*) eleven animals fed for periods of from four to fourteen weeks on a rice diet; (*d*) five animals fed for varying periods on a diet of porridge or oats; (*e*) twenty-two animals fed for periods of from twenty days to eight months on a raw meat diet. The uteri of the animals fed on milk and bread soaked in milk approximated most nearly to the type of structure in the wild rat. The use of what the author called a "nonphysiological diet"—for example, exclusive flesh, rice, or porridge—induced in the great majority of cases a modification in the structure of the uterine mucosa. The change was most profound in animals fed from weaning on an exclusively flesh diet. In such animals the development of the uterus was also most interfered with. This structural change was associated with sterility, and it was found that the rats fed on meat alone, especially when this diet was begun immediately after weaning, were almost invariably sterile.

Dr. Campbell's experiments are interesting, but they are hardly conclusive. We doubt whether a diet of milk or milk and bread is any more physiological for rats after weaning than is one of grain or meat; a mixed diet is probably more normal for them as it is for man. Our assumed arboreal ancestors were probably prolific on their diet of nuts and fruits, yet, as we do not know who they were, it may be that this particular species became extinct, and survived only in our less remote progenitors, who lived by the chase and gave birth to numerous offspring while gorging, in the intervals of hunger, on the raw flesh of other animals and probably also that of their own kind. It may be, however, that the evil effects of a merely exclusive meat diet were counterbalanced in the case of our forebears by the active life led in dodging their enemies and hunting their prey, for we know that even now the man who leads an active outdoor life can partake of a larger amount of flesh food with impunity than his sedentary brother. There is no doubt that an excess of meat in the dietary, as an excess of food of any kind, is injurious, and the more so the less the eater lives in the open air: but it may be also that it is the quantity rather than the quality of food that injures the eater. As regards the diminished birth-rate, there are undoubtedly some factors at work other than voluntary restriction, *pace* Mr. Roosevelt, and it may be that an excess of meat in the dietary, combined with a sedentary habit, is one of these factors. If so, we, at least the female portion of us, must resort to the carbohydrates; but the late Dr. Schenk told us that such a diet would result in the production of children of one sex only, and this, unless we can make practical the Christian Science theory of parthenogenesis, would be the surest road to race suicide.

SANITARY METHODS AND THE MARCH OF SANITATION.

No one can deny that progress in sanitation has been the means of saving innumerable lives and of lengthening the lives of as many others. Whether this result will be for the ultimate good of the human race is another question altogether. Some men whose opinions carry weight contend that many lives are thus saved which are not worth the saving, and hold that the "survival of the fittest" is the doctrine which, if carried into effect, will most benefit the community at large. Nevertheless, it must be admitted that the object of modern medicine and of modern sanitary science is to preserve as many lives as is possible and to lengthen life to its utmost limit. This being so, the nations in the van of civilization naturally vie with each other in their efforts to gain this end.

At one time, and not so many years ago, Great Britain led easily in all matters pertaining to sanitation. She was the pioneer of modern sanitary methods. Of recent years Great Britain has lagged in this respect, and in no department of sanitation more conspicuously than in that relating to the control of her milk supply. In the *Lancet* of May 25 is a decidedly sharp criticism by Dr. J. H. Garrett,

Medical Officer of Health of Cheltenham and a well-known authority on the subject, of the present methods of administering the public health acts in England. It would not interest readers of this journal to notice all the points brought forward by Dr. Garrett, many of which are of a purely local nature, but the main features of his criticisms should be of interest to sanitarians in all parts of the world. The principle upon which English sanitary control is now founded is that of decentralization. The power is vested in local authorities, and Dr. Garrett shows up the defects of this system. He is of the opinion that "the narrow minds of rural councillors are always unduly affected by consideration of expense and by that conservative policy of let-be which permits of the fool's paradise in which they are usually so content to dwell." The writer further draws attention to the notorious fact that the capacity in individuals of ruling the mass of the populace with good effect is not a common one, and the smaller the district the less likelihood of its containing men capable of becoming effective rulers.

A select committee on the Housing-of-the-Working-Classes Act has issued recently a report on the housing of the working classes in rural districts of Great Britain, which shows the hopelessness of any effective administration of the act by the existing rural district councils and the officers whom, in the capacity of sanitary authorities, they have appointed to serve them. In a few words, it would seem that the sanitary laws of Great Britain are in the main sufficiently good, but that in most instances, in rural districts at least, they are not properly enforced.

It has been proposed frequently during recent years that Great Britain should have a great central department of government with plenary executive powers over the whole country. This proposal is opposed to the essence of British government, which is based on the principle, as in this country, that the people should rule themselves, find out what they want, and find out how to get it. As a matter of fact, people cannot be made sanitary by law, and this statement especially applies to those with the freedom-loving Anglo-Saxon traditions. Both in the United States and in Great Britain the inhabitants to a large extent must work out their own salvation in matters sanitary as in other matters.

The mission of the skilled sanitarian is to educate and point the way. Of course, in large cities at any rate, it is necessary to have ordinances the enforcement of which is calculated to preserve health. But, on the whole, education of the masses will bring about the desired results more effectively than the most stringently enforced laws.

THE INFLUENCE OF METEOROLOGICAL CONDITIONS, REFUSE HEAPS, ETC., ON THE BACTERIAL CONTENT OF URBAN ATMOSPHERE.

The number and character of the bacteria in the air of cities are influenced by particular meteorological conditions, such as rain and wind, and by other conditions not meteorological, such as refuse heaps, density of population, proximity to lines of traffic, etc. Tests to ascertain the extent of these influences are difficult to make, since it is seldom possible to repeat an expriment under exactly similar meteorological conditions. In the *Scottish Medical and Surgical Journal* for June, 1907, C. J. Lewis publishes the results of a series of experiments, showing what a notable influence the above named conditions exert. He used both the gravitation and filtration methods to estimate the number of organisms present in the air, and as most of these organisms will grow on a gelatin medium, under aërobic conditions, at a temperature of 15° C., this method of culture was adopted. Of the meteorological conditions rainfall and wind exert the greatest influence. Rain washes the organisms out of the air into the soil. The result of Lewis' examinations showed that the extent of purification of air by rain corresponds in direct ratio with the duration and heaviness of the fall. Thus, a heavy rain of four hours reduced the organisms in the air from 162 per square foot per minute to 28, *i.e.* by eighty per cent.; two hours of heavy rain effected a reduction of only sixty per cent.; in the case of light rain the reduction amounted only to thirty per cent., the place of observation being the same in each case.

As regards the effect of wind, Lewis found repeatedly that there was an excess of organisms to leeward over those to windward. Furthermore, not only the quantity but the quality of the organisms was changed. On the windward side there were found generally harmless organisms, while to leeward were organisms of putrefaction and of sewage origin. When the plates obtained on the windward side of the town were incubated at 15° C. he found from eleven to seventy-five organisms per square foot per minute, while on agar plates obtained at the same time and place, and incubated at 37° C., only from one to thirty organisms were found. This is of clinical significance, as it shows that to windward of a town the air does not contain many organisms capable of growth at blood temperature—a characteristic attribute of organisms pathogenic to human beings.

With respect to dust particles, Lewis found that there was a numerical relation between them and the organisms deposited at the same time and place. When the number of organisms was high the count of dust particles was high. Very high numbers were obtained in places where there was heavy and rapid traffic, showing definitely the effect of the latter. It is a somewhat trite observation that the number of organisms in the air is smaller in winter than in summer. Lewis found that this general rule usually held, yet on several occasions (the conditions of wind, humidity, rain, and barometric pressure being the same) he found fewer organisms deposited on warmer days; he therefore believes that the influence of temperature is overestimated. Barometric pressure and humidity in themselves were not constantly associated with any direct variation of the number of organisms.

As regards the influence of locality, densely populated districts, refuse heaps, and polluted soils were all found to have a notable influence upon the numbers and character of the organisms present in the atmosphere. On a sewage farm *B. coli communis* and the streptococcus frequently appeared on the plates. In the proximity of slums the average of

several observations showed 949 organisms per square foot per minute, contrasting strongly with 132 per square foot per minute obtained in less crowded districts. In the misfortune which befell New York last week in the strike of the drivers of the Street Cleaning Department, as a result of which heaps of refuse accumulated in the streets, an attempt was made to reassure the public by the statement that the accumulated refuse was only an offense to the olfactories, but that it offered no danger to health. This is incorrect, for with the vastly increased number of microorganisms in the air, there must be a proportionate increase of pus cocci and other pathogenic germs. The period around the murderous Fourth of July was a bad time for this condition of filth accumulation to exist.

The Internal Treatment of Acne.

Acne is a condition which has brought forth more methods of treatment, with few exceptions, than any other disease of the skin. Local procedures have perhaps been exploited to a greater extent than those of a general or systemic character, and the assumption is often made that the lesion is local rather than constitutional in its main features. Kapp (*Therapeutische Monatshefte*, March, 1907) again calls attention to the fact, already sufficiently proved, that intestinal derangement in many instances constitute the underlying basis upon which the disposition to the production of acne depends. In addition to these we have at the time of puberty a number of other conditions which enter into the problem. A skin poorly nourished and insufficiently supplied with blood offers less resistance to the entrance of whatever bacterial organisms may bring about the characteristic pustulation of this organ than one which is in a healthy and well nourished condition. Kapp's experiments throw considerable light on the importance of intestinal derangements in the etiology of acne. He found in the urine of thirty young patients afflicted with the disease a marked increase in the quantity of indol, indican, and a number of similar substances. This is evidence of intestinal decomposition of high degree, and as diminished intestinal peristalsis is usually present, particularly during the period of puberty, we have at hand the two main factors in the production of the lesions. Treatment should therefore be directed towards reducing fermentation and increasing peristalsis in the intestine. Kapp suggests precipitated sulphur (1.0) and menthol (0.25) two or three times daily as an efficient remedy. All forms of acne, even of the severest types, were markedly improved after three or four months of treatment, and in many cases were permanently cured. Local disinfectant treatment was at the same time employed in all the cases in order to prevent the spread of the infection. Notwithstanding these favorable results, Kapp admits that there are certain features in the relationship between intestinal decomposition and inflammation of the follicles of the skin, which cannot as yet be fully explained.

An Unusual Bladder Case.

The ideal method of removing concretions or foreign bodies from the bladder, namely by the action of solvent substances, is unfortunately impracticable in many instances. A remarkable case in which this procedure was successfully carried out is reported, however, by Lohnstein in the *Berliner klinische Wochenschrift*, June 10, 1907. The patient was a young man under treatment for obstinate cystitis, the nature of which could not be discovered. All ordinary etiological factors, including the introduction of a foreign body into the urethra, were energetically denied by the patient, but a cystoscopic examination revealed at the vertex of the bladder a yellowish white, smooth mass of about the size of a walnut. As it did not appear to be adherent to the bladder wall, the suspicion was aroused of its being a foreign body lighter than water, and therefore floating at the vertex of the bladder. As such a body could hardly be of either cork or wood the patient was taxed with having inserted wax into his urethra, and finally admitted that five months' previously, in order to allay an itching sensation in the urethra, he had made from a wax candle a bougie-like mass which he had allowed to escape into the bladder. Shortly afterward the vesical symptoms had set in. The author succeeded in removing the mass at two sessions by injecting into the empty bladder small quantities (15 to 25 gm.) of benzine, which the patient retained from 10 to 45 minutes. No noteworthy local or general symptoms followed the procedure, the vesical symptoms promptly subsided, and subsequent cystoscopic examination demonstrated the absence of the foreign body. The amount of wax obtained by evaporation of the benzine used was about 5 gm. The case affords an interesting illustration of the diagnostic value of cystoscopy, and is also remarkable for the fact that no incrustation of the foreign body took place during its long sojourn in the bladder.

Glycocoll in the Diagnosis of Gout.

The excretion of glycocoll is chiefly found in leukemia, gout, and during the crisis of a pneumonia. The only other pathological change common to these conditions is the increased production of uric acid, so that glycocoll is possibly a decomposition product of the latter. To prove this L. Hirschstein (*Zeitschrift für experimentelle Pathologie und Therapie*, Vol. 4, No. 1, 1907) administered to several patients large quantities of uric acid internally, and in each case found glycocoll in the urine. As a rule the output of uric acid and glycocoll showed almost parallel curves. This was not so, however, in cases of gout, in which there is an excess of uric acid in the blood, with a diminished amount in the urine, and where glycocoll appears in its stead. During the height of an attack of gout, there is a sudden increased excretion of uric acid, and, coincidently, the glycocoll disappears from the urine. While glycocoll is not present in all cases of gout, a probable diagnosis of this disease may be made when it is found in the urine without any other cause to account for it, and especially if there is at the same time a diminution in the amount of uric acid excreted. The appearance of glycocoll in the urine following the ingestion of uric acid, the constant relation which glycocoll and uric acid bear to each other in pathological conditions, and the experiments of Wiener and Schittenhelm, who obtained glycocoll by splitting up uric acid with certain ferments, all go to prove that this substance is a derivative of uric acid.

The Excretion of Euglobulin.

Euglobulin is an albuminoid constituent of the blood serum which may be separated from the latter by triple saturation with ammonium sulphate.

Although this substance has been shown to be of a complex composition and capable of being broken up into a number of parts, it may, for practical purposes, be considered as a single body. Joachim found in a case of chronic nephritis associated with amyloid degeneration of the liver, spleen, and kidneys that there was an increased excretion of euglobulin in the urine, and later on Wallerstein made a similar observation. The application of these findings for clinical purposes has recently been made the subject of an investigation by Zak and Necker (*Archiv für klinische Medizin*, Vol. 88, No. 3), who made a careful clinical and microscopical study of a series of cases. They believe that if the patient is kept under observation for a sufficiently long time the reaction can always be elicited in the presence of amyloid degeneration, although the quantity of euglobulin varies within wide limits. These variations could not be traced to either temperature changes, the food, increased cachexia, or improvement in the general condition, and they are of such a character that the writers venture to speak of an intermittent euglobulinuria associated with amyloid degeneration. Although the absence of this reaction does not permit us to exclude the diagnosis of the latter pathological condition, its presence seems to afford a pretty definite evidence that this lesion is present.

The Etiology of Trachoma.

It is not astonishing that the discovery of the spirochetes present in the lesions of syphilis should have led to renewed activity in investigating the etiology of various other diseases of obscure origin. Among these is trachoma, and several authors have lately published observations which seem to have a bearing on the causative agent of the affection. Leber has described the occurrence in the trachoma follicles of large cells with numerous peculiar inclusions. Halberstadter and Prowazek, working in Java, have recorded somewhat similar observations, and in addition to the larger inclusions have described much smaller granules occurring in pairs and present in the protoplasm of the epithelial cells of the conjunctiva. Greeff (*Deutsche medizinische Wochenschrift*, June 6, 1907) describes similar bodies, but states the important fact that they are to be found also in the cells of the follicles themselves. These bodies are only about one-fifth the size of ordinary cocci and may be seen both in sections and in the hanging drop. While it would be premature to attach too much importance to these observations, and many steps must be cleared up before they can be regarded as standing in an etiological relationship to trachoma, their discovery is a noteworthy observation, and it may be that in retrospect they will be found deserving of greater consideration than they seem entitled to at present.

The Diagnosis of Renal Calculus.

The diagnosis of nephrolithiasis is oftentimes attended with no small difficulty, and additions to its symptomatology are to be welcomed. Bittorf (*Münchener medizinische Wochenschrift*, June 4, 1907) believes that hyperesthesia to pressure of the testicle of the affected side is a characteristic sign of this condition. In a considerable number of cases of other renal and abdominal conditions examined for this sign negative results were obtained. The author explains the mode of causation of the symptom by assuming that it is due to a stimulation of the spermatic plexus, which either originates directly from the renal plexus, or has a common origin with this from the aortic plexus, and so is likely to be directly implicated. This view receives substantiation from the fact that ovarian hyperesthesia was present in a case of renal calculus in a woman. The symptom has not as yet been tested in a sufficient number of cases to establish its specificity, but it should prove an interesting subject for further observations. If found to be reliable it would prove of much service in differentiating the puzzling cases of right-sided abdominal pain in which renal, biliary, or appendicular involvement may exist.

News of the Week.

New Immigration Law.—The new immigration law became effective on July 1. Its provisions are designed to raise the standard of those admitted to the United States, and the head tax on all aliens entering the country is raised from $2 to $4. The excluded classes are increased by adding to the list of ineligibles imbeciles, feeble-minded persons, persons afflicted with tuberculosis, those certified upon medical examination to be mentally or physically defective to such an extent as to affect their ability to earn a living, and all persons coming into the United States for any immoral purposes. One section makes the decision of a board of special inquiry final, not only as to the rejection of aliens afflicted with loathsome or dangerous contagious diseases, or with mental or physical disability bringing them within the excluded classes, but also as to persons afflicted with tuberculosis.

For the Education of Poor Mothers.—In conjunction with the work of Junior Sea Breeze, the open-air camp hospital established last year at Sixty-fourth street and the East River for the purpose of taking care of sick babies, a staff of nurses has been organized whose function it will be to visit the homes of the poor and give the mothers instruction in the care of their small children. This work is to be carried on in the district between Thirty-ninth and Eighty-ninth streets and from Fifth avenue to the East River, with Junior Sea Breeze as a center. There will be ten nurses, each in charge of a section of this district, and another staff of ten nurses has been provided to do similar work in the districts adjoining the recreation piers. A physician is to be stationed by the Board of Health, and a kindergarten teacher by the Board of Education on each pier. A third staff of visiting nurses will devote their attention to maternity cases, in the interest of Caroline Rest, the convalescent home of the New York Association for Improving the Condition of the Poor, for mothers and newborn babies, at Hartsdale, N. Y. The funds for the Sea Breeze work and the visiting nurses are provided by Mr. John D. Rockefeller. Last year the Sea Breeze Home on Coney Island received 23,051 children for stays of varying duration, and it is expected that 25,000 will be provided for this year at a cost of about $50,000, collected by voluntary subscriptions.

Conviction of a Christian Scientist.—A Christian Scientist arrested some weeks ago on the charge of having permitted his six-year-old daughter to die of bronchopneumonia without medical attention, was found guilty last week in the Court of Special Sessions of having violated that section of the Penal Code which makes it a misdemeanor for a parent to fail to provide medical attendance for a minor. The sentence may be a fine of $500, a year's imprisonment, or both. An effort was made in behalf of the

prisoner by Justice Deuel to have the trial stopped on the ground that the new law regulating the practice of medicine, which went into effect on May 13, specifically exempts from punishment persons carrying out the practice of the religious tenets of any church. Whether this section of the law does or does not apply to the practice of Christian Science healing has not yet been settled by court decision, but it was decided that it was inoperative in the present case, as the child had died before the law went into effect. It is possible that this provision in the new law will be declared ineffective in regard to minors in any case.

An Appeal for Clean Streets.—Twenty-five organizations, among which are the Academy of Medicine, the Automobile Club, the Charity Organization Society, the City Club, the Women's Municipal League, and the East Side Civic Club, have presented to Mayor McClellan a memorial asking for better care of the streets. This action was not suggested by the strike of employees of the Street Cleaning Department, but the petitioning bodies were forced thereto by the utter failure of the Commissioner to keep the streets even passably clean. Four suggestions are made in the memorial as follows: (1) As a preventive measure of very great and obvious importance, that the Police Department be directed to enforce the very clear and comprehensive provisions of law that forbid the unnecessary soiling or littering of the streets. (2) That citizens be informed more adequately as to what is required of them, and as to the penalties for offenses against these laws. (3) That the working system of the Street Cleaning Department be thoroughly reorganized, and that the Department itself be required to conform to all laws applicable to it. (4) That the asphalted pavements throughout the city be washed daily, and that the most improved type of flushing machines be secured for that purpose. There is, as the memorialists remind the Mayor, an abundance of authority in the law as it stands for action under any of the above heads.

Free Milk in Jersey City.—The Health Board of Jersey City has decided to establish a depot in the basement of the City Hall for the free distribution of pasteurized milk. Poor women presenting prescriptions from a physician for pasteurized milk for infant feeding will receive it without charge. It may also be obtained without a prescription by paying the cost of the bottles. The free dispensaries maintained at drug stores for several summers will be abandoned and the dispensaries' appropriation will be used to support the free milk depot. Substations will be opened in the basements of public school buildings.

Opium in the French Navy and in China.—The use of opium in the French Navy is alleged to have become exceedingly prevalent among both officers and men. The Minister of Marine has been obliged to issue an order that the names of officers suspected of using the drug be reported to him, and has forbidden the presence on the vessels of any articles used in opium smoking. A new edict has been issued in China which orders all officials to use every effort to carry out the provisions of the anti-opium edict previously issued, and commands an investigation into the quantity of land at present devoted to the cultivation of opium. In addition to threats of punishment for officials dilatory in executing the regulations, rewards are promised for those who are active in the work.

Absinthe Not to be Forbidden.—The Commission on Hygiene of the French Chamber of Deputies has rejected the bill recently introduced which provided for the total prohibition of the sale of absinthe on the ground that its consumption was a menace to the prosperity of the country. The commission refused to sanction the measure, alleging that it could not discriminate between absinthe and many others liqueurs, but it recommended the passage of a law forbidding the sale of the cheap imitations sometimes sold under the name of absinthe.

Chicago Physicians Honored.—The honorary degree of LL.D. was conferred on Dr. George H. Simmons at the commencement exercises of the Northwestern University, held June 20, and the honorary degree of A.M. was conferred on Dr. James B. Herrick at the annual commencement exercises of the University of Michigan, held June 20.

Resignation of Prof. Carmalt.—Dr. William H. Carmalt, for thirty years professor of surgery in the Yale Medical School, has resigned this post and been made professor emeritus.

Tent Hospitals for Militia.—Major T. J. Sullivan, Surgeon of the Seventh Regiment, I. N. G., favors the idea of tent hospitals, such as the regular army has adopted, and the surgeons of the Illinois National Guard are almost unanimously in agreement with him.

New Hospital for Chicago.—On June 16 ground was broken for the new People's Hospital at Twenty-second street and Archer avenue. This building will be three stories high and of pressed brick and steel construction. The building is to be erected under the auspices of the People's Hospital Association, of which Dr. I. C. Gary is secretary and William D. Schaefer is president.

Bequests to Charitable Institutions.—Bequests amounting to two million dollars provided for in the will of the late John C. Proctor of Peoria, Ill., among other charitable objects, are to be devoted to the establishment of a laundry to give employment to boys and girls, a manual training school for boys, and an orphanage. The sum of $350,000 has been set aside for a home for the aged and $300,000 for the Cottage Hospital.

Woonsocket (R. I.) District Medical Society.—At its annual meeting held in Providence on June 20 this organization elected officers for the following year as follows: *President*, Dr. E. D. Clarke; *Vice-President*, Dr. John J. Baxter; *Secretary*, Dr. William F. Barry; *Treasurer*, Dr. George R. Smith.

North Missouri Medical Association.—Officers as follows were elected at the annual meeting of this organization held in Gallatin on June 22: *President*, Dr. James Hanks of Brasbear; *Vice-Presidents*, Drs. Knott of Keytesville and D. F. Hanna of Gallatin; *Secretaries*, Drs. E. C. Grim of Kirksville and Oliver McEuen of Shannondale; *Treasurer*, Dr. Robert Haly of Brookfield.

Oregon State Homeopathic Medical Society.—At the thirty-first annual meeting of this society held in Portland on June 12 officers were elected as follows: *President*, Dr. Charles Billington of Portland; *Vice-President*, Dr. J. S. Bishop of Forest Grove; *Secretary*, Dr. H. S. Nichols of Portland; *Treasurer*, Dr. Emma J. Welty of Portland.

In Honor of the Late Dr. John H. Packard.—The visiting staff and former resident physicians of the Pennsylvania Hospital have decided to have painted a portrait of the late Dr. John H. Packard, one of the surgeons to the hospital from 1884 to 1896, to be hung in the institution,

in recognition of his services as teacher, surgeon, and author.

Death of Prof. Schüller.—Prof. Maximilian Schüller of the University of Berlin died last week of cancer of the stomach. Prof. Schüller was an ardent advocate of the parasitic theory of cancer, and had made many contributions to the literature of the subject. He had also prepared a serum which he believed at one time to be curative of the disease which killed him.

Obituary Notes.—Dr. Charles F. W. Ebner of St. Louis died in that city on June 18, at the age of seventy-six years. He was a native of Germany and received his medical education in the universities of Halle and Goettingen. He came to this country in 1852, and had practised in Chicago, Baltimore, and Millard, Neb. He served as regimental surgeon in a New York infantry regiment during the Civil War.

Dr. James D. Folsom of St. Johnsbury, Vt., died on June 20 after a long illness. He was born in Wheelock in 1828, and was graduated from the medical department of Dartmouth College. He had practised for many years in Lancaster, and had been a resident of St. Johnsbury for thirty-five years.

Dr. Charles E. Severance of Brattleboro, Vt., died on June 20, at the age of seventy-three years. He was born in Leyden, Mass., and received his medical education in the College of Physicians and Surgeons of this city. He practised in Shelbourne Falls, Mass., from 1861 to 1885, and then practised for a time in Newark, N. J. In 1890 he removed to Brattleboro.

Dr. George W. Carr of Providence, R. I., died on June 18, at the age of seventy-three years. He was born in Pawtucket, and was graduated from Brown University in the class of 1857. He received his medical education in the National Medical College of Washington and the University of Pennsylvania Medical School. During the Civil War he held several medical positions in the army, and at one time was Brigade-Surgeon of the Fourth and Sixth Army Corps. At the close of the war he resumed practice in Providence, and in 1868 was appointed physician to the Rhode Island State prison. He was Brigade-Surgeon of Rhode Island for several years, and was made Medical Director of the militia when that body was reorganized. When the Rhode Island Hospital was established he was its first surgeon, and he held the post until 1888. A few years ago he retired from active work.

Dr. Franklin J. Voss of Brooklyn died suddenly on June 27, in his fifty-sixth year. He was graduated from the medical school of the University of the City of New York in 1885 and had practised in Brooklyn ever since.

Dr. Frank Horace Getchell died at Philadelphia on June 27, at the age of seventy-two years. He was a great-grandson of Dr. Obediah Williams, a surgeon in Stark's regiment during the Revolutionary War, and he was graduated from Dartmouth Medical College in the class of 1862 and from Jefferson Medical College in the class of 1871. During the Civil War he served as surgeon in the Third Maine Volunteers until his health failed, when he was detailed to army hospitals at Philadelphia.

Dr. John Benson of Chatham, N. B., died on June 24, at the age of sixty-eight years. He had practised for many years in Newcastle and in Chatham.

Dr. A. W. Corner of Butte, Mont., died on June 21 of septicemia contracted from a patient. He was born in Missouri and received his medical education in Washington University, St. Louis. He had practised in Butte about six years.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HOSPITAL SUNDAY—INTERNATIONAL RED CROSS CONFERENCE—PATHOLOGICAL SOCIETY'S FINAL MEETING AND PRESIDENT'S ADDRESS—TO RELIEVE OPIUM-EATERS—OBITUARY.

London, June 14, 1907.

The week began with Hospital Sunday and collections were made in most places of worship. So far as can be ascertained, the contributions promise to equal those of last year, but time must elapse before the accounts can be made up, as many remittances have yet to arrive.

The eighth International Red Cross Conference has occupied attention this week. It was opened at the Medical Examination Hall on Tuesday by Field Marshal Earl Roberts, who read messages from Queen Alexandra and the Empress of Russia. The delegates of the participating countries numbered 150. The Queen's message, as president of the British society, expressed the "greatest pleasure" in welcoming all on the occasion of the first meeting on British soil, and the assurance of her "warmest and most heartfelt sympathy in their united endeavors to further still more the great scheme for relieving the sufferings of the sick and wounded." The delegates are invited to Buckingham Palace for to-morrow. Messages were also received from Miss F. Nightingale and the presidents of the French and German societies.

There is also an exhibition of appliances and devices for finding, raising, and transporting the wounded, which has a claim to be called international, as eleven countries contribute to it—not with a view, however, of giving a comprehensive display of all Red Cross appliances, but rather to set before the delegates such devices as any constituent society may consider worth the attention of the others. Here were a brace of trained ambulance dogs, exhibited by Major Richardson, whose breeding and training of them has done much to promote their use and give a new meaning to the phrase "the dogs of war." For raising and removing the wounded on litters and stretchers many devices are shown. The applications of the bicycle to ambulance work form a notable exhibit. Aluminum splinting, recommended by Sir F. Treves, for dealing with all kinds of fractures on the battlefield, and many surgical appliances are also on show, and have proved very interesting to the delegates and others.

On Wednesday the report of the Augusta fund was submitted and discussed. In this it is mentioned that a year's interest had been contributed towards the erection in Copenhagen of a model hospital of fifteen to twenty beds, to be a model clinical hospital during peace and to be for treatment of officers in war time. Another year's interest went to the German society for work in Manchuria. One of the German delegates remarked that the late Empress Augusta had desired the fund to be used for good works in time of peace. He proposed favoring a plan for giving a sum to enable four to six delegates to visit and report upon Red Cross institutions in various countries. This was agreed to and four delegates appointed.

Other subjects discussed were the organization of help for prisoners of war, the extension of work in time of peace, the misuse of the Red Cross, and the need of legislation in some countries to prevent such abuse.

On reassuming the sittings yesterday an invitation for the ninth conference in 1912, to meet in Tokio, was received with cheers. General Prion read a paper on the position and functions of women in hospitals and sanitary work in time of war. Professor Renault followed with a paper on Red Cross work at sea. The conference adopted a resolution in favor of cooperation between the Admiralty and societies for the succor of the sick and wounded.

Sir F. Treves presented a report on the British society. It was announced that the primary duty of aiding the sick and wounded rested on the medical departments of the navy and army and that the Red Cross Society should offer such additional comforts and help as might be considered beyond the reasonable scope of the official bodies. The Red Cross Society has been officially recognized as the channel for voluntary offers of assistance and it is therefore an object of its care to examine, systematize and coordinate all such offers and by preventing overlapping and waste to render them of the utmost value.

Mr. Geo. H. Makins of St. Thomas' Hospital submitted a paper on the rôle of the society during maritime war. He said in many countries ships could not be provided by societies, which might undertake the equipment and personnel for medical officers and nurses (male or female) would be required in numbers far above those which a navy could supply. Stores and dressings would differ little from those of military warfare, though the rarity of rifle wounds and the frequency of extensive shell wounds, burns, and scalds rendered a much larger type of dressing necessary.

Dr. Nagao Ariga, professor of international law, Japan, read a paper on the work of the Japanese Red Cross during the late war and the principles by which it was guided. This paper was full of detailed and official information and showed the excellent work of the Japanese society, which employed 5,170 persons during the war, organized into 152 relief corps, and spent over half a million of money. The society prepares everything during peace and places all at the disposal of the army and navy on the outbreak of war. It submits in every detail to the authority of the army and navy and attempts nothing independently, so that it is not semi-official, as some have supposed, but a purely private association, supported by the subscription of its 1,300,000 members. The Emperor is president, but that is only a matter of honor, and his subscriptions are purely personal. The society extended its work to the sick and wounded of the enemy. There is strict centralization in the control and financial work and the consequent exclusion of all volunteer members of the Relief Corps, except those who are ready to undertake real earnest work in time of war.

Lieutenant-Colonel F. Rho, an Italian delegate, said that the Italian officers who saw the work of the Japanese society were deeply impressed with its excellent organization.

M. Pérouse presented a report on the ambulance appliances in France and moved a resolution that the improvization of the means of removing the wounded from the battlefield deserved the study of all Red Cross societies, and exhorting those members who lived on frontiers to practice in peace those duties which would devolve on them on the outbreak of war. This was carried.

Dr. von Petersen reported on the relief work of the Russians in the war with Japan, from which it seemed that the Russian forces were ill-prepared for the requirements of the sick and wounded.

The conference may be pronounced a success. You will afford us space for mention of the entertainments offered to the delegates, which were on the usual scale; the visit to Windsor Castle yesterday; the reception of the Lord Mayor in the evening being most prominent. To-morrow will be the reception by the Queen at Buckingham Palace.

The Pathological Society on the 4th instant passed its final resolution declaring itself dissolved. It has become the pathological section of the Royal Society of Medicine. At the meeting in question there were two or three characteristic communications. Dr. F. P. Weber, for instance, exhibited an osteolipoma of the base of the brain, about the size of a haricot bean. Its site had been between the optic tracts corresponding with the infundibulum. The small bony focus contained red marrow. It was remarked that a similar case had been recorded by Dr. Bristowe in an early volume of the Society's transactions.

Drs. Sambon and Seligmann exhibited specimens of ten new hemogregarines which they had found in the red corpuscles of different snakes in the Zoological Gardens. In all the organism was capsulated and there were lines on the capsules which were held to indicate lines of future cleavage through which the parasite escaped. Free forms were found in the blood. The authors had traced the penetration of the red corpuscles. They had observed the parasite also in the leucocytes. For the completion of its life history the parasite had to reach the intestine of a blood-sucking host.

Dr. Nabarro had observed that sometimes leucocytozoa occurred in the blood of rats. In some cells two parasites were present, presumably of different sexes.

The experimental production of goiter was the subject of a communication by Dr. Bayon, who did not accept the theory of embryonic residue. He said parenchymatous goiter began in hypersection and epithelial proliferation, and the accumulation of epithelium was a further irritant and could not be got rid of as "casts" in the kidney are. Such changes Dr Bayon had produced in animals by injecting toxins into the thyroid artery. Ligature of this artery led to localized necrosis and the formation of nodular adenomata. Anything which damaged the epithelium would incite enlargement of the gland. Graves' disease had been observed to follow infective diseases. In some cases of myxedema and cretinism there had been previous acute infection. Such infection might ultimately lead to atrophy of the thyroid.

The President, Dr. Pye-Smith, gave a valedictory address in which he mentioned the successive presidents since the foundation of the society in 1846. It is a roll of great physicians and surgeons who saw the importance of pathology and did much to promote its study. At the foundation Dr. Pye-Smith said pathology was but the handmaid of medicine, but now it has attained an independent position and is itself the foundation or "institute" on which rests the prevention and treatment of disease. Morbid anatomy was the beginning of rational pathology. Then came experiments on living animals, such as those of Harvey, Hunter, and others. The rise of bacteriology was the third chapter. The fourth is chemical pathology, now in its infancy, but probably destined to open new paths to investigation. Especially fruitful will probably be the borderland between animal and vegetable pathology. Recent investigations on nerve degeneration dealt with conditions, chemical as well as histological, and opposite changes have been studied. But the future of experimental pathology, said the president, lies on the knees of the Royal Commission on Vivisection. Let us hope the result will be greater freedom. The minute anatomy of disease is not complete; the chemical aspect of pathology is only begun; nowhere is the ground more promising than on the confines of physics and physiology, between botany and zoology, between chemistry and physics. Professor Farmer has shown how complicated may be the structure of a single cell. But complex or simple, it still baffles every attempt to explain its functions and their mechanism.

In the Museums Journal of the Malay States there is an account of a drug alleged to render the opium eater indifferent to the privation of his indulgence. It is an infusion of *Combretum Sundiacum* leaves and is said to have been discovered by some Chinese woodcutters who had run out of their tea and tried to replace it by the leaves of this creeping plant. In the Malay States the drug has been largely tried in the prisons and lock-ups, where the opium eating prisoners suffer intensely at first from the sudden deprivation of their drug. It is said that the infusion of the *Combretum Sundiacum* alleviates their sufferings and does not substitute another habit in place of opium eating.

An injunction in Chancery has been granted restraining Dr. Geo. L. Eastes from carrying on his pathological laboratory. The judge said it had been shown that the work of Dr. Eastes was for the advantage of medical practitioners throughout the country, but the covenants of the lease precluded it from being carried on on those premises. The injunction therefore must be granted, but Dr. Eastes must be given a reasonable time to remove his laboratory, the injunction would therefore be suspended until September 29.

A letter from India gives the news of the death of Major David Macbeth Moir, A.M., M.D., professor of anatomy in the Calcutta College. Born in 1860 he took his M.D. in Edinburgh in 1899 after being in the Indian Medical Service. He was in the Chin-Lushai expedition, 1889-90, for which he received the medal with clasp. In 1891, up to which time he had remained in the military medical service, he was appointed to various offices on the civil side, including that of professor of anatomy and surgeon to the hospital, Calcutta. He attained the rank of major in 1900.

Dr. Samuel Lawrence Gill died on the 11th inst. within seven days of attaining his eighty-fourth year. He was for many years surgeon to the N. L. Railway. Took the M.R.C.S. and L.S.A. in 1846, L.R.C.P. Ed., 1859. He contributed on puerperal mania and recovery from traumatic tetanus to the medical press and the doctor

OUR PARIS LETTER.

(From Our Special Correspondent.)

PROPHYLAXIS OF SYPHILIS—THE COMBAT AGAINST TUBERCULOSIS—THE PRACTITIONERS' CONGRESS—ARTERIAL GRAFTING—NECROLOGY.

PARIS, April 25, 1907.

DELORME presented an interesting study on the prophylaxis of syphilis before the Académie de Médecine. He was able to determine by statistics obtained from the army records that primary syphilis is more than three times less frequent in soldiers than among civilians of the same age, and that the same relationship obtains for the other venereal diseases. It has been well known that morbidity through venereal diseases has been progressively decreasing in the French army owing largely to the efforts that have been made toward the moral and hygienic education of the soldiers. Delorme directed attention to the dangers of clandestine prostitution and to the relative safety afforded by the regular houses under medical supervision. Public health requires protection through legal measures and the speaker

was of the opinion that the Académie should intervene in this question and continue the crusade against syphilis begun in 1888. Fournier expressed his agreement with the views of Delorme and suggested that the Académie should appoint a commission to consider the steps that should be taken.

Prof. Robin proposed to the Académie a tentative plan of clinical organization for the purpose of combating tuberculosis. He considered that the antituberculosis campaign should comprise the following elements: Prophylaxis, education of the public, treatment of the patients, and aid to the patient and his family. Robin described the organization of the Antituberculosis Bureau of the Hôpital Beaujon. In this the patients are divided into seven classes: (1) The nontuberculous, (2) the pretuberculous, (3) patients who have friends in the country and who are sent back there by the bureau, (4) the incipient cases, which are sent to the sanatorium of Angicourt, (5) patients with extrapulmonary lesions, (6) consumptives requiring hospital treatment, (7) patients that can be cared for at home. The bureau distributes codliver oil, meat, gelatin, and medicines; it supervises the disinfection of dwellings and the improvement of their sanitary condition. It also offers material aid to the patient and secures work for those who are able to do it. The work of the bureau cost, in 1905, 6,803 fr. for 935 patients; that is to say, 7.27 fr. per patient.

The Congress of Practitioners held its sessions in Paris from April 12 to 14. More than 14,000 practitioners and over a hundred medical societies were enrolled for the congress. The success of the convention was all the more striking since it was unexpected, for this was the first time that a similar assemblage has been held in France. This was the first occasion on which the French practitioners have united to discuss the future of their profession, and both the members of the Faculty of Medicine, with their years of experience, and the enthusiastic students took active part in the sessions of the congress. The inaugural address was delivered by the president, M. Gairal. Among the topics discussed was the question of reforming the teaching methods. Hirtz and Caussade presented a paper on the hospital as a center of clinical instruction; they pointed out that clinical instruction could be obtained only at the bedside and that a theoretical education was merely of supplementary value. In order to render the facilities of the hospital more available for educational purposes, they suggested that the medical faculties should be enlarged and opportunities be given for every man of merit to rise to the highest rank. They also suggested that the institution of Privat-Docentism, which exists in nearly all countries, should be established, and that the hospitals should be made the centers of medical education from the clinical and therapeutic standpoint. Huchard also discussed at length the question of medical education and suggested numerous ways in which the present complicated system could be simplified and rendered more practically useful.

Gairal read a paper on the right of the patient to select the physician, and urged that all mutual aid societies should organize their medical service in such a way as to respect the independence of their members and to give them the right to choose their physicians.

Before adjourning, the congress decided to maintain a permanent committee, whose function should be to supervise the relation between the medical profession and the public and to educate the latter in regard to the legitimate rights of the physician.

Delbet read before the Sociétie de Chirurgie a report on an attempt at arterial grafting in man.. The patient was a man of seventy-four years, suffering from general arteriosclerosis, not of syphilitic origin, and who had a rapidly growing femoral aneurysm. Delbet decided to excise the aneurysm and to attempt to reestablish the continuity of the vessel by the implantation of a section of artery supplied by M. Schwartz, who, while Delbet was extirpating the aneurysm, performed an amputation of the thigh for a case of osteomyelitis of the femur. The limb was at once taken to Delbet, one of whose assistants dissected out the popliteal artery. A portion of this, about 9 cm. in length, was then introduced in place of the aneurysm that had been removed. Unfortunately the vessel walls of the patient were so friable that it was impossible to apply the necessary sutures and ligature of the artery itself could be carried out only at a level above Hunters' canal. The result of the operation was what was apprehended, for some days later gangrene of the foot appeared and the leg had to be amputated at its lower third. The patient's condition at present is satisfactory. Tuffier reported a case in which a successful arteriovenous anastomosis performed for obliterating arteritis of the femoral artery had resulted fatally in a few days as the result of gangrene and thrombosis of the femoral artery.

During the past month the medical profession has suffered the loss of two of its prominent members, Prof. Poirier and Dr. Ferré. Poirier died suddenly of an affection of the liver at the age of only fifty-three years and after having attained all the honors that the medical career can offer. While still a young man he had been made Professor of Anatomy in the Faculty of Medicine in Paris, hospital surgeon, and officer of the Legion of Honor. He has left behind numerous scientific works; his original contributions on the synovial membranes, on the ganglia of the sympathetic system, and on the lymphatics are classics. His treatise of surgical anatomy which he wrote in collaboration with Prof. Charpy is of great importance, and his courses of anatomy were always very popular because he possessed to an unusual degree the faculty for instruction and knew how to address his students with eloquence and magnetism. He was popular with the undergraduates and was always able to hold the attention of the most restless audience. Only a short time ago he presented before the Académie de Médecine a communication of unusual weight on the prophylaxis of cancer, as a result of which a formal society having this object in view was formed.

Dr. Ferré, physician of the Hospice de Bicêtre, died at the age of fifty-four years. By means of his work in experimental biology he was able to play a large part in revolutionizing psychological methods. Among his very numerous works were "The Pathology of the Emotions," "The Neuropathic Family," "Degeneration and Criminality," "Animal Magnetism," "Disorders of the Intellect," "Aphasia and Its Various Manifestations," "The Home Treatment of the Insane." His noteworthy experiments on muscular work and on the physiology of voluntary motion, on muscular fatigue, and the reaction time, have all contributed to establish his reputation as an investigator and thinker.

SOME ASSUMED OBJECTIONS TO VIVISECTION.

To the Editor of the Medical Record:

Sir:—May I be allowed space for a brief presentation to your readers of certain aspects of the reverse side of vivisection?

Thoughtful members of the prime great profession—that of medicine and surgery—are ever ready to admit, along with other deductions from history and from human nature, that some of their methods may prove mistakes, and that some conclusions reached by this generation may be discarded by the next. Persons interested in the small controversy about vivisection believe that method and many of its conclusions to be among the doomed. Their reasons for such an expectation are generally such, perhaps, as appeal to the lay mind rather than to the expert, and yet one of those reasons, I think, is of the opposite character.

What Lawson Tait called the "prima facie" objection to vivisection is, of course, the fact that certain branches of it involve a considerable amount of severe vicarious pain. The causing of such pain is in itself increasingly repugnant to our age and any practice involving it is placed somewhat upon the defensive. It is true that the slaughter house, the fur-trader's line of traps, the milliner's purveyor of plumage, the seal fisheries, the sportsman's "bag," and too often the farmyard and stable, furnish other examples of vicarious suffering, and that for ends (except the first) immeasurably meaner than the experimenter's. But, on the other hand, a real difference between vivisection and these other practices is indicated by the fact that in slaughter, hunting, the fur and feathers trades, and domestication of animals, their sufferings are largely incidental. Much is caused by haste and bustle; much by ignorance, and much by the greed of untrained minds. But in the laboratory ignorance, greed, haste, and bustle are rare or unknown. Vivisection is not full of these incidental and thoughtless cruelties. The "prima facie" objection to it is the essential character of its resultant pain. When we have established the woodfall trap, the humane and hygienic abbatoir—when the sportsman leaves gun for camera, and the docked horse is no more seen, vivisection, if freely practised, must still be a secret from children, and a sorrow to the informed.

Its supporters cannot, however, allow this to be a sufficient reason against the practice which inflicts pain for a noble end. Nor is it a sufficient reason from the exclusively logical standpoint, though psychologists and historians may discern a large truth in Froude's remark that "the heart often corrects the folly of the head." There are other reasons why vivisection, well considered, appears a doubtful benefit to the whole nature of man. The late Master of Balliol was accustomed to say that in his opinion vivisection tended to effeminatize the race. May not its tendency indeed be to appraise too highly the prolonging of the individual life? Dr. Jowett perhaps undervalued

the pains and miseries of mankind. But can we, even to relieve these, afford to reduce the courage of our race, the risking spirit of our forefathers? Are we in no danger of being taught to value our bodily comfort at too high a figure?

Mr. H. C. Merwin, lately of the Massachusetts Legislature, believes in the reality of such a danger. His able article in the *Atlantic Monthly* some five years ago, presented with remarkable clearness this aspect of the situation. Certainly there is a moral danger in all laying of burdens upon vicarious shoulders. A society like that of Greece, founded upon slave labor, was not politically disciplined to withstand the shocks of change. A church like that of the fifteenth and sixteenth centuries, assuming a vicarious responsibility for the sins of the people, was full of the seeds of a reformation. The gravest danger to our race from vivisection is perhaps a moral danger.

But there is, in the minds of a minority, a serious physical danger allied with this. If we may look, in an increasing degree, to preventive serums to insure our health, shall we not be severely tempted to neglect those laws of hygiene which have never become a habit? This is, I believe, a very sandy spot in the foundations of vivisection. Large classes of the human race now knowingly (whether of their own accord or through economic pressure) violate the laws of health. They bend their backs over ledgers, or sewing machines; they surfeit themselves with excitement; they breathe exhausted air; they neglect sinks and drains, and feast upon "gamey" meats. But they believe the penalty may be paid, as the disease is studied, by proxy. A series of rabbits, or of mice, which have observed the laws of nature, may be caught and inoculated with the desired culture, their reactions studied, and conclusions drawn from the application of various remedies. Nature has decreed health to the rabbits and sickness to certain classes of men. Man, however, subverts natural justice, and substitutes a vicarious order. But are scapegoats ever wholesome for those who escape? Will they be ultimately benefited by the success of a system of "getting well quickly" rather than keeping well slowly? And is Nature's justice so readily outwitted?

This will be regarded, perhaps, as a theoretical question. The practical results of vivisection, on the other hand, are in everybody's mouth. Our family physicians rely on diphtheria antitoxin, and we hasten to be vaccinated if smallpox breaks out in the neighborhood. And when we read of Midshipman Aiken's case, and think it might have been some near friend of our own, we think a shade more lightly of the sufferings of animals in vivisection.

But a careful estimate has yet, I think, to be made of the direct profit and loss of the practice. As the accounts of a cooperative commercial enterprise are balanced and audited, so might the records of this institution be balanced by candid experts, and audited by the general public—the most interested party. A long list would then, I think, have to be made out of wasted skill, wasted time, and wasted pain—not, indeed, wasted in the worst sense, as time and skill are wasted by the idle, or the enemy to society, but wasted as were the efforts of great minds in the past to discover the philosopher's stone, or the kingdom of Prester John. People of thirty years old and more can recall several "lymphs" and "elixirs" on which large hopes were founded, only to end in disappointment.

To the layman vivisection appears to be placed in a dilemma. If the structure of animals closely resembles that of man, the presumption must be that their sufferings, too, in general resemble the sufferings of man in like conditions; and this would make the vivisection question exceedingly grave. If, on the other hand, animals differ radically in structure from man, this would seem to cast many doubts upon the general utility of experiments upon them, and to suggest that the conclusions drawn from such experiments can be of little or no value until tested in the clinic.

S. N. CLEGHORN.

MANCHESTER, VT.

PILOCARPINE IN SYPHILIS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR,—Regarding the use of pilocarpine as an adjuvant in the treatment of syphilis, as advised in the MEDICAL RECORD of June 15, I would say that three years ago, studying symptomatology, I remarked, though never *coram publico*, that mercury causes ptyalism, as does potassium iodide, and I asked myself whether the specificity of both does not lie in their sialogogue action, by which the syphilitic toxins or microorganisms are removed from the body. Of course, the next thought was the use of pilocarpine in syphilis as a very well known sialogogue, but I never made any experiments with it. Two years later, after having studied Ehrlich's sidechain theory, I came to another theoretical result, which differs entirely from the explanation of Dr. W. J. Robinson, the author of the mentioned article. It is a known fact that after administration of pilocarpine to an animal, in which are found certain antitoxins, the quantity of the latter increases, this being due to the action of pilocarpine upon the internal secretion. In case of injection of a certain quantity of toxins into an animal, in the blood of which are the specific atagonistic antitoxins, the toxins disappear, being neutralized, in a shorter time, when an injection of pilocarpine follows. Knowing Ehrlich's sidechain theory, one can easily come to the following conclusions: (1) By injection of pilocarpine the increased quantity of antitoxins and antibodies would antagonize the circulating toxins in blood and lymph. (2) The organs secreting the antibodies would be freed in a shorter time from these antibodies, by which action those organs would be less endangered by the action of the antigens. (3) The same organs would be stimulated, secreting a greater quantity of antibodies.

How mercury and the salts of iodine act in syphilis is still unknown. It is only known that they are the best remedies in the treatment of syphilis. They cannot be called specifics for syphilis, as they do not cure the disease, removing only the symptoms for a shorter or longer time, and do not, like the antitoxins of diphtheria, neutralize entirely the toxins of the disease. There is a possibility that mercury and the salts of iodine are only stimulants to some organs, producing under their influence a greater number of the hypothetical antibodies against syphilis. In case they fail to do it, for unknown cause, which is rare, pilocarpine will be the best stimulant as a remedy against syphilis, as the facts adduced by Dr. Robinson show.

Progress of Medical Science.

New York Medical Journal, June 22, 1907.

Hygiene in Relation to the Heredity of Disease.—After some observations on hygiene in general, P. A. Morrow enumerates a long list of diseases in which the hereditary element has been definitely established. In order to bring modern hygiene to bear on this problem the author states that the most radical preventive hygienic measure would be to prevent the physically unfit from marrying, but he realizes the impracticability of this in the statement that the influential motive to marriage has never been the improvement of the race. Selective breeding cannot be applied to improve the race. But the principle of selection should be so applied as to exclude from marriage and parentage certain types, the reproduction of which tends to deteriorate the species, for thousands of children who die before being born, or come into the world with the mark of death on them, are victims of the ignorance or disobedience of parents to the terrible laws of pathological heredity. The end to be attained will, in the author's view, be treated by education rather than by restrictive legislation. The birth of a tainted, diseased, or degenerate child should not be regarded as an "act of Providence," but as a fateful expression of the parents' transmitted tendencies. The educational propaganda should begin with the medical profession. The causes which underlie hereditary phenomena should be carefully studied by physicians, their significance rightfully interpreted and the resulting knowledge be popularized for the enlightening of public opinion. The more essential condition is that the springs of heredity should be kept pure and undefiled from the taint of syphilis, tuberculosis, insanity, alcohol, and other hereditary factors in the production of a vitiated progeny.

Surgical Aspects of Some Digestive Disorders from the Standpoint of the Internist.—J. R. Arneill declares that countless sufferers from gall-bladder disease, ulcer of the stomach, and duodenum, and their secondary crippling effects on stomach, bowel, and pancreas are daily being treated for bilious attacks, gastralgia, and dyspepsia, with small prospect of permanent relief and with great danger of subsequent development of malignant disease of these organs or at best of extreme debility, neurasthenia, and ill health from prolonged starvation and suffering. The author admits that unsatisfactory results sometimes follow upon surgical intervention, but he urges on all physicians that it is their duty to insistently and persistently recommend and advise exploratory operations, when a conscientious, intelligent, and scientific examination of a serious case leaves doubt as to the diagnosis and treatment. This recommendation will apply most often to dyspeptic cases, in which there is a suspicion of cancer; also to obscure

conditions in the right hypochondrium, in which gastric ulcer and gall-bladder disease are suspected, but not proved. The dangers of exploration are much smaller than those of procrastination. Thousands of lives will be saved, awful suffering assuaged, and the sum total of human happiness wonderfully increased, when the exploratory incision becomes the routine practice in such cases.

Experimental Immunity to Colon and Typhoid Bacilli.—This paper recounts the experimental results of V. C. Vaughan and M. Wheeler. The authors refer to their previous work on the effects of bacterial and other proteids and their split products on animals. They then describe the two portions into which the cellular substances of the colon and typhoid bacilli have been split. These two portions they designate respectively as poisonous and nonpoisonous, and their attempts at immunization with the latter. Their views are condensed into the following propositions: (1) All the proteids with which they have worked contain a poisonous group, and the probabilities are that this is true of all proteids, be they bacterial, vegetable, or animal. (2) Proteids may be split into poisonous and nonpoisonous groups, either artificially in the retort or in the animal body. (3) The splitting up of the proteid in the animal body is due to a proteolytic ferment which is the product of certain cells, probably the mesothelial cells that line serous membranes and the blood-vessels. (4) This ferment is specific for the proteid which calls it into existence. (5) Their conception of the origin and nature of these specific ferments is as follows: The cell is made up of molecules; the molcules consist of atoms, and the atoms of electrons. The molecule may be likened to the universe, composed of suns, planets, and satellites. These are in harmonious and rhythmic motion. The molecule of the foreign proteid introduced into the body has a structure similar to that of the cell molecule, and when one is brought within the attractive range of the other, one or the other, or both, must undergo certain disturbances. Suppose that an atomic group is split off from the animal cell and enters the attraction sphere of the molecule of the foreign proteid, then the harmonious arrangement of the atoms and electrons of the latter will be affected; indeed, the molecule may be disrupted as completely as it is in the retort under the influence of dilute alkali. The residues evidently have the same effect on the cells of the body that the proteids from which they come do, and in this way may be explained the specific action of the residues. The special group broken off from the cell molecule depends upon the composition of the proteid which comes within its attractive sphere, and it seems that its residues contain that portion of the molecule of the foreign proteid which possesses this property of bringing into existence, or rather of activating, its own specific ferment. The ferment is, according to the authors' conception, a portion of the animal cell, an atomic group within the cell molecule, and does not become a real active ferment, or it is not activated until the foreign proteid comes within its sphere of attraction. It occurred to them that if this theory has much of truth in it they might test it. They thought that the introduction of a small portion of the residue might give some immunity immediately. They therefore injected doses of 25 mg. of the colon and 12.5 mg. of the typhoid residue into the abdominal cavity of guinea pigs, and 30 minutes later inoculated these animals intraabdominally with living cultures, and found that the colon animals had in that short time acquired an immunity of five units and the typhoid one of six units. However, they found that larger immunizing doses did not give results so good, and this is easily explained by supposing that this ferment set free or activated by the residue is in part used up in its reaction with the residue itself. The reason why multiple doses repeated at intervals give us a higher degree of immunity than single doses may be due to more cells being acted upon or to the accumulation of the ferment in the blood. The theory of the modus operandi of the residue which they have offered is tentative, and they hope to be able to investigate it further.

Journal of the American Medical Association, June 29, 1907.

Non-Operative Treatment of the Middle Turbinate.—J. A. Stucky says that the primary cause of the average case of disease of the middle turbinate is systemic, and the exciting factor of the acute attack is not so much exposure to cold and draughts as injudicious eating and drinking. The condition is not seen in any one who lives plainly and uses sparingly, or not at all, alcoholics, coffee, tea, and sweets. The patients are generally highly neurotic, good livers, and lead inactive lives; they are troubled with frequent colds, stuffy feelings in the head, stopped-up nose, and accumulation behind the palate. They are usually more or less constipated, their complexions are abnormally florid or muddy, and they complain of the liver. Such symptoms and history lead him at once to suspect indicanuria, with probable excess of uric acid. When there is an abundance of indican in the urine in such cases, there is no satisfactory or permanent relief until this is thoroughly eliminated, the diet corrected, and the bowels regulated. The treatment he recommends is mainly the thorough cleansing of the intestinal tract and the use of salicylates, well diluted and in moderate doses. He rarely finds local treatment necessary except in the beginning, when the nasal cavity is cleansed with physiological saline solution containing a small amount of menthol and adrenalin, the latter not in stronger solution than 1 in 7,000. He sums up the treatment of disease of the middle turbinate as follows: (1) Correct faulty intestinal metabolism; (2) restore bodily resistance; (3) cleanse, soothe, and protect the diseased or irritated area.

The Early Symptoms of Pernicious Anemia.—J. A. Lichty takes up the question of whether or not it is possible to diagnose pernicious anemia by the early symptoms before the appearance of the characteristic blood picture of the disease. In his cases, achylia gastrica with diarrhea was present in fourteen, and in nine it was a very early symptom. In one case it seemed to have been present thirty-five years before the blood condition was recognized, in another it was present eight years before the blood picture developed, and in still another it was present six years before. The nervous symptoms may be early or late, but in only one of his six cases with early nervous symptoms did they appear before the signs in the blood were found. The cardiovascular are the least characteristic early symptoms, in only one of his five cases presenting them as such did he properly interpret them before finding the pathognomonic blood signs. He is, therefore, unable at present to describe a symptom-complex indicating pernicious anemia before the occurrence, or discovery of the blood changes, but he believes that such a symptom complex exists.

The Opsonic Treatment of Paresis.—Accepting Ford Robertson's *Bacillus paralyticans* as the cause of general paralysis of the insane, as confirmed by inoculation and agglutination tests made by him, J. D. O'Brien reports the results of opsonic treatment of seven paretics at the Massillon (Ohio) State Hospital. The patients were selected from the ordinary run of paretics admitted. The beginning dose of the vaccine was a small one, but enough to evoke a satisfactory response, and then it was regulated by the length of the negative phase till a satisfactory standard dose for each individual was secured. There was marked improvement in all the cases reported, nearly all passing in a comparatively short time from a marked demented or excited condition into one of partial or nearly complete remission. The change from the negative to the positive phase was attended with marked mental improvement, within a few hours. The control cases of paresis, while under the same treatment, with the exception of the vaccinations, showed no improvement.

The Lancet, June 15, 1907.

Meditations on Gout.—These "meditations" were penned by C. Mercier during an attack of gout, himself being the sufferer. He asks why, if the kidneys act freely and the greater part of accumulated uric acid is excreted, the toe joints should suffer. His explanation is that the blood is supersaturated with the acid, that there are more urates in it than the kidneys can manage, but that the urates carried on to the toe exist in the blood in some combination which renders it proof against renal elimination. The author believes that gout is due to uric acid, but not to mere excess of this. During an attack the acid must exist in some peculiar combination. The combination is not always the same in every attack in a given individual. There are probably many urates which agree in being noxious and being more or less proof against renal elimination, but which differ in their pathological effects. In regard to joint localization in the disease, the author suggests that the articular cartilages may secrete a substance which has a predominating power in breaking down the harmful combination, separating the urate from the blood, breaking down the combination of the acid with its (presumably) organic ally and converting it into sodium urate. This action may be conservatism toward the general organism and analagous to the action of the blood-cells in separating bacilli and consuming them. When a pernicious combination of uric acid is circulating in the blood, damaging the kidney, thickening the arterioles, perhaps perverting the action of the brain, it may be as valuable and as conservative for this combination to be broken down, even at the cost of a gouty joint, as it is to have a brood of streptococci extruded, even at the cost of an abscess.

Notes of a Case in Which Glycosuria, Depending Upon Cholecystitis and Cholangitis, Disappeared After Drainage of the Bile Ducts.—The history of the case is given by C. A. Mansell Moullin his patient being a stout middle-aged woman who had had an attack of biliary colic eleven years previously. The attack referred to in the title began with vomiting and severe abdominal pain, jaundice quickly supervening, and constipation. The patient's low general condition precluded immediate operation. The bowels were cleaned out and the symptoms gradually abated, so that in two weeks it was possible to open the abdomen. A calculus was found in the common duct and the gall-bladder was found full of small facetted calculi of the ordinary variety. A drainage tube was fastened into the common duct, another in the gall-bladder, and two long gauze drains were inserted, one in front of the common duct and the head of the pancreas (which appeared normal), and the other into the right renal pouch. Recovery was uneventful. The interest of the case lies in the disappearance of the glycosuria as soon as efficient drainage was established. From the repeated attacks of cholecystitis which the patient had had (there was a vague history of several others besides these two of which the dates were known), and from the fact that she had lost much weight in the past few years it is probable that there was some degree of chronic pancreatitis, though the pancreas had not the stony hardness usually present in this condition. But the disease must have been merely of the interlobular type, and not as yet have involved the islands of Langerhans. Under the influence of septic inflammation spreading up the duct the interacinar portion of the gland became involved and glycosuria followed. Fortunately, as soon as a thorough drainage was established the inflammation subsided so quickly that to all appearance no permanent injury was inflicted upon the gland. Hitherto glycosuria, when occurring in association with cholecystitis and cholangitis, has been regarded as a bar to operation. As a matter of fact, it is one of the strongest arguments in favor of it. Thorough drainage not only prevents further injury being inflicted upon the gland by the septic organisms that have invaded it, but, as in the above case, restores the gland to the condition in which it was before the septic invasion took place.

Causes of Colitis, with Special Reference to Its Surgical Treatment.—J. P. Lockhart Mummery presents a tabulation of thirty-six cases under the headings of sex, age, symptoms, duration, and conditions found. In several cases no cause whatever could be ascertained. A large variety of lesions were respectively present in the other cases. In a group of five cases cancer of the sigmoid flexure was present, in quite a large group catarrhal inflammation was observed, showing varying degrees of congested mucosa, hypertrophy, small polypi, papilloma of rectum with malignant base, ulcerations, etc. The author has found this latter group the hardest to cure, although the patients are easily made more comfortable. A group of cases presented inflamed appendices. The author says we do not know exactly how appendicitis may cause colitis. He advances the following possibilities: (1) Appendicitis is generally accompanied by inflammation of the ascending colon and cecum, and in some cases this inflammation of the colic mucosa may spread into the transverse colon and even reach the sigmoid flexure. It is not uncommon during the operation for appendicitis to find that the inflammation has spread into the ascending colon. (2) Appendicitis may also cause colitis by the formation of adhesions between the appendix or cecum and the sigmoid flexure. These adhesions by interfering with the lumen of the gut either through direct constriction or by causing abnormal flexures and angles may result in a local inflammatory process being set up and the symptoms of colitis subsequently develop. The first result of such adhesions is usually constipation, to be followed in a shorter or longer time by diarrhea and the passage of mucus. (3) It would seem probable that a chronically inflamed appendix may cause symptoms of colitis by the frequent discharge of septic material into the bowel. It has become customary to describe the colon and rectum as septic channels, though there is no justification for this. As a matter of fact, septic organisms are not at all usually numerous in the large intestine and the pathogenic flora of the mouth is far more numerous than that of the rectum and colon. Even the skin is a more common habitat for septic organisms than the colon. It is not surprising therefore that a chronically inflamed appendix which is continually discharging septic organisms into the bowel may be the cause of colitis, just as we know that carious teeth and septic conditions of the mouth can cause gastritis. We have very positive evidence that removal of an inflamed appendix will in many cases lead to a complete cure of colitis.

British Medical Journal, June 15, 1907.

On the Radical Cure of Urethral Stricture by Internal Urethrotomy.—J. Macmunn says that the ideal instrument in the operation named should stretch the tissues, cut the roof or floor, cut to any depth desired, cut the widest as well as the narrowest coarctation, localize the lesion it divides, and cut from before or from behind. The object desired is to restore the normal urethral axis, thus avoiding friction in urination, to remove as much of the obstruction as possible commensurate with safety and to avoid unnecessary section of healthy tissue and blood vessels. The author then describes and figures his favorite urethrotome. Section should be made at the point where the stricture mass is greatest, where bleeding will be least, and where drainage may be best secured. In regard to the amount of section, the author's rule is to cut a little over the surgical capacity of the urethra immediately anterior to the stricture, usually 1 mm. more. Besides cutting, sounds should be passed. The author prefers short wedge-shaped sounds and as large as possible, and with pressure to get them into the incision. He says that urethral sounds should have a curve only half the usual size. They should pass through the stricture only, not into the bladder. Chill and shock will then be rare. Postoperative treatment calls for: (1) Wound healing so that a permanent gap is left; (2) guarding the wound against urine contact for a time; (3) avoidance of complications.

Plugging the Posterior Nares.—A. O. Ward advises the following method: Pass the usual double thread (preferably of silk) through either nostril, using for the purpose an eyed probe, if the surgeon possesses one of sufficient length. Such an implement is a nearer approach to a Eustachian catheter in caliber than a Bellocq's sound or any urethral catheter; as all aurists soon learn, even a small Eustachian catheter sometimes fails to pass. Repeat the process through the other nostril with a fresh thread. The loose ends hanging from the mouth are now tied to each other and round a plug of gauze or of lint, and are cut short. By pulling on the ends hanging from the nostrils, and aided by a finger in the mouth, the plug is dragged up behind the soft palate, and more or less to one posterior nostril as may be necessary. Next (if required) plug one or both anterior nares, thread the silk ends through a piece of rubber tubing, and tie either in front of the nose or across the cheeks and behind the neck. Keep these ends long, so as to control the plug when, next day, it is pushed back into the mouth for removal. By this plan the discomfort to the patient is reduced to a minimum.

Berliner klinische Wochenschrift, June 10, 1907.

An Unusual Case of Prostatectomy.—Posner says that the longest period of catheter life that has been relieved by a prostatic operation is a case lasting twenty-eight years in which Freudenberg performed the Bottini operation. Freyer, Legueu, and Young have reported instances of twenty-four, eighteen, and fourteen years respectively. In view of these observations and of a case of his own, he urges resort to operative measures even in cases of the longest standing. His own patient had not voided urine spontaneously for eighteen years, and had had one vesical calculus removed by litholapaxy. The suprapubic operation was done and a second calculus removed. The prostate was enucleated and weighed 112 g. Recovery was uncomplicated and six weeks later the patient was able to urinate spontaneously at intervals of two or three hours without any residual urine.

Some New Conceptions of the Living Cell; Its Chemical Structure and Its Functions.—Victor C. Vaughan at the close of his paper says that a most important group of cellular secretions is made up of the ferments or enzymes. All the ferments are cellular products. A ferment is a substance of definite chemical composition formed by the rearrangement of the atomic groups within the cellular molecule. The action of the ferment, while it is determined by the cell which produces it, is not concerned in the "energy traffic" constantly going on between the molecules of the cell which produced it and other molecules external to this cell. With our present limited knowledge of the chemistry of the cell molecule, it is impossible, at least in many cases, to distinguish between the chemical reactions resulting from cell metabolism, and those due to ferments. The function of a ferment is to hasten chemical reactions which take place, but far more slowly, without the presence of the ferment.—*The Canadian Journal of Medicine and Surgery.*

Book Reviews.

THE JOHNS HOPKINS HOSPITAL REPORTS. Studies on Hypertrophy and Cancer of the Prostate. Volume XIV. Baltimore: The Johns Hopkins Press. 1906.

THIS volume follows one entitled "Studies on Urological Surgery." It contains three articles by Dr. Hugh H. Young, Associate Professor of Genitourinary Surgery at the Johns Hopkins University. The first of these deals with the treatment of prostatic hypertrophy by conservative perineal prostatectomy, and includes an analysis and a detailed report of 145 cases. The second is an appendix to the first, and deals with new procedures for the radical cure of rectourethral fistulæ, while the third is devoted to a study of forty cases of carcinoma of the prostate, four of which were treated by a radical operation. An appendix contains sixty-four complete case histories.

The present volume is a veritable thesaurus of statistical and other valuable information on prostatic hypertrophy and cancer of the prostate. A very large clinical material enters into its compilation, and it represents undoubtedly one of the most important modern contributions to the subject. The conservative variety of the perineal type of prostatectomy is advocated, following a technique original with Young and already familiar through his previous writings. In the treatment of rectourethral fistulæ following prostatectomy, the author advocates preliminary suprapubic cystotomy followed by a closure of the rectal and urethral fistulæ through the perineum. The work on carcinoma deals chiefly with the early diagnosis and the radical cure of the disease. One of the interesting conclusions reached by this study is the fact that cancer occurs in about 10 per cent. of hypertrophied prostates. The malignant process may begin as an isolated nodule in the prostate, and a case which for years has been evidently one of hypertrophy may suddenly develop signs of malignancy. Marked induration in men over 50 should be regarded with suspicion. When operating it is best to remove small sections of the prostate first, and to make frozen sections. These can be got ready in about six minutes, and if malignant disease be found the radical operation should be performed. The latter should include the removal of the seminal vesicles, the vasa deferentia, and most of the vesical trigone, with the entire prostate. In four cases this operation gave remarkably good results.

NOUVEAU TRAITÉ DE MÉDECINE ET DE THÉRAPEUTIQUE Publié en fascicules sous la direction de P. BROUARDEL et A. GILBERT, Professeurs à la Faculté de Médecine de Paris. XII. MALADIES DE LA NUTRITION: GOUTTE, OBÉSITÉ, DIABÈTE. Par H. RICHARDIÈRE, Médecin de l'Hôpital des Enfants-Malades, et J.-A. SICARD, Médecin des Hôpitaux de Paris. Avec 15 figures dans le texte. Paris: J. B. Baillière et Fils, 1907.

THIS new fascicle of the system of medicine edited by Brouardel and Gilbert, treats of the group of nutritive disorders commonly considered under one heading: gout, obesity, and diabetes. The volume resembles in scope and makeup its predecessors in this comprehensive treatise, and the diseases considered are dealt with in great detail from every viewpoint, discarding, however, obsolete material and including the most modern data and methods. For example, the use of high-frequency currents in diabetes will be found discussed with sufficient fullness, and the modern methods of diagnosis have received careful attention. No attempt has been made evidently to "cover" the modern literature of the subject, and bibliographic references are scanty. On the other hand, the published material on the diseases treated of has been sifted and quotations of entire paragraphs or even pages abound from a number of authorities, chiefly French. The style of the book is that clear, clean-cut phraseology which makes modern French medical writings so easy and so pleasant to read. The charming description of gout by Sydenham has been quoted in full in a most interesting historical review of this malady, and the volume opens with a specially prepared introduction to this group of diseases, which reads like a confession, so frank is it in its plea of ignorance as to their true inwardness.

TUBERCULOSIS AS A DISEASE OF THE MASSES, AND HOW TO COMBAT IT. Fourth issue, revised and illustrated. Prize Essay. By S. A. KNOPF, M.D., New York. Director in the National Association for the Study and Prevention of Tuberculosis; Associate Director of the Clinic for Pulmonary Diseases of the Health Department; Visiting Physician to the Riverside Sanatorium for Consumptives of the City of New York, etc. New York: Fred P. Flori, 1907.

THIS fourth edition of Knopf's well-known prize essay contains four new sections dealing with home hygiene, school hygiene, the installation for the sanatorium treatment at home, and a short historical review of the antituberculosis movement in the United States. This pamphlet is now published in twenty-one different languages, and thus can reach people in and from all parts of the civilized world. As a book for the masses who, more than others, need the information herein contained, Knopf's essay is unsurpassed.

A MANUAL OF OBSTETRICS. By A. F. A. KING, M.D., Professor of Obstetrics and Diseases of Women in the Medical Department of the George Washington University, Washington, D. C., and in the Medical Department of the University of Vermont, etc. Tenth Edition, enlarged and thoroughly revised, with 301 illustrations and three colored plates. Philadelphia and New York: Lea Bros. & Company, 1907.

FROM its first appearance, King's Obstetrics has occupied an enviable position as a text-book. In this tenth edition some errors have been corrected and some obsolete methods omitted; the chapter on Fecundation and Nutrition of the Embryo has been almost entirely rewritten; considerable changes have also been made in the chapters on Pelvic Deformities, Cutting Operations upon the Mother, Mutilating Operations upon the Child, Placenta Prævia, and Puerperal Septicemia. Forty new engravings and three colored plates have also been added to this edition. The general plan of the work remains as before; it is a first book, characterized by accuracy, brevity, and simplicity of statement. Many generations of students have found this book to be a most reliable guide, and it can still be recommended as probably the best small book on the subject.

TRAITÉ D'HYGIÈNE, Publié en Fasicules sous la Direction de MM. BROUARDEL et MOSNY: HYGIÈNE ALIMENTAIRE, par J. ROUGET et CH. DOPTER, professeurs agrégés au Val-de-Grace. Paris: J. B. Baillière et fils, 1907.

THE present volume forms the fourth part of the large treatise on hygiene edited by Brouardel and Mosny, and deals with dietetics and alimentary hygiene. It is the work of two of the professors at Val-de-Grace, the military medical training school. The first part of the book deals with the various articles of food, their composition, and other characteristics. A brief section deals with the mode of preparing food by cooking. Then follow chapters upon the various spices and condiments, the preserved foods, and the methods of preparing them, including the use of antiseptics. The different beverages are next considered in the same manner. An outline of the ordinary adulterations of foods and their detection follows. The next portion of the book deals with food more particularly from the physiological and medical aspects. The qualitative and quantitative relations of various diets are considered, not in respect of different diseases, but in a general way, as for example overfeeding, underfeeding, vegetarian diet, meat diet, etc. Finally, a very complete and comprehensive discussion is presented of the various disease conditions transmitted through food, and their prevention, *e.g.* parasites (trichinæ, etc.); bacteria (typhoid fever in oysters, etc.). Here are given summaries of the recent researches in these special fields of hygiene. The subject of tuberculosis is handled in a brief but very practical and sane manner. The book may be recommended especially to students of hygiene and to food inspectors and health officers. It is not particularly adapted for use by clinicians, save as a work of reference.

HYGROMEDRY. By HENRY EMERSON WETHERILL, M.D., etc. Fourth Edition. Revised, enlarged, with many new plates. Philadelphia: Published and Illustrated by the author, 1906.

"HYGROMEDRY," according to Dr. Wetherill, is the art of measuring the moisture of the body "and of its surrounding environment." The "hygromed" is the instrument devised by the author for this purpose, and consists of a hygroscope made up of a fine copper spiral, over which is stretched a hygroscopic membrane. The moisture enters the instrument through appropriate openings, and acts upon the membrane, which thereupon acts upon the spiral and the indicator points upon the scale of the instrument. If the author's claims as to the accuracy and sensitiveness of his instrument are correct, the "hygromed" is undoubtedly useful in determining the amount of surface moisture. This amount, however, is of but slight clinical importance, and any very great variations from the normal are quite readily detected without any instrument by the sense of touch. The book is ornamented by a portrait of Dr. Wetherill in his uniform of Lieutenant in the Pennsylvania militia, but though this undoubtedly adds to the value of the book, it does not entirely compensate for careless proofreading and inelegancies in diction which more or less mar the work.

Society Reports.

NATIONAL ASSOCIATION FOR THE STUDY AND PREVENTION OF TUBERCULOSIS.

Third Annual Meeting, Held at Washington, D. C., May 6, 7, and 8, 1907.

[Special Report to the MEDICAL RECORD.]

(*Continued from Vol. 71, page 1054.*)

Tuesday, May 7.—Second Day.

GENERAL MEETING.

THE PRESIDENT, DR. HERMANN M. BIGGS OF NEW YORK, IN THE CHAIR.

The Campaign Against Tuberculosis in the United States.—By Dr. LIVINGSTON FARRAND of New York, Executive Secretary of the National Association for the Study and Prevention of Tuberculosis. Dr. Farrand's address was a survey of the general situation in the movement against tuberculosis in the United States, and called particular attention to the advances which had been made during the two years in which the National Association had been actively at work. The chief task of the association had been one of education, and it was recognized by its founders that organization was a prime necessity in the successful solution of the tuberculosis problem. The chief effort, therefore, had been directed toward the formation of State and local associations for the prevention of tuberculosis, which had as their function the conducting of the campaign in their respective commonwealths and localities. It was shown that two years ago there were seven States with organizations operating on State lines, these States being New Hampshire, Vermont, Pennsylvania, Maryland, Ohio, Indiana, and Illinois. During the past two years eight more, namely, New Jersey, Delaware, North Carolina, Georgia, Kentucky, Minnesota, Iowa, and Washington had formed State associations, making fifteen now definitely in existence and affiliated with the National Association. In addition to these, the plans for State organization were far advanced in Massachusetts, Rhode Island, New York, Virgina, Michigan, Missouri, and California, so that twenty-three States were now practically provided for, and from the point of view of State organization and geographical distribution the situation was well in hand in all parts of the country with the exception of certain sections of the South and far West. It was the plan of the association to push its campaign of organization through the southern States during the coming winter. An active and efficient society had also been formed during the past winter in Porto Rico, where the work of education and relief was being carried on along modern lines. Of even more interest was the growth of the movement in the larger cities of the country. By the census of 1900 there were thirty-eight cities with populations of over 100,000. When the association took up its work two years ago there were definite organizations for the prevention of tuberculosis in fifteen of these. During the past two years active societies had been formed in eleven others, making twenty-six of the largest cities in the country where an organized campaign of prevention was being carried on. Of the remaining twelve, plans for organization were far advanced in at least six, and it was hoped that during the coming year the situation would have been met in the entire list. Recognizing the fact that the tuberculosis problem was one which must always be met in the community in which it was found, the organized work had been pushed into smaller towns as well as in the larger cities, and there were now seventy-four local organizations in the United States affiliated with the national body. The rapid growth of this movement was shown by the fact that two years ago there were nineteen special local societies; a year ago the number had increased to thirty-two, and now there were seventy-four, an increase of nearly 300 per cent. in two years. Probably the most efficient single means of education has been the Tuberculosis Exhibition, which was organized in November, 1905, and opened in New York City under the auspices of the National Association and of the Tuberculosis Committee of the Charity Organization Society. Since that time the exhibition had been shown in sixteen of the larger cities of the country, as well as in Toronto and Mexico City. This exhibition, which had aroused intense interest wherever it had gone, showed to the public in simple, graphic form the facts regarding tuberculosis, its infectious character, its preventability, and its curability. Charts, photographs, models of sanatoria, sleeping shacks, window-tents, etc., were shown and lectures and demonstrations were given in each city during the time of the exhibition. The attendance thus far had been 372,000, and in all places it had proved a marked stimulus to the local campaign against the disease. The success of the exhibition had been so great that a number of permanent local exhibitions had sprung up as a result. In certain cities, such as New York and Boston, they were sent from quarter to quarter through the State, and were carrying the information regarding tuberculosis and its prevention to those classes of the community among whom it was particularly prevalent and who were particularly difficult to reach. In certain cases the States had seized the idea and had formed exhibitions which were being sent from town to town in an attempt to reach those citizens who could not have an opportunity of seeing the exhibition in the larger centers. Two years ago State sanatoria for the treatment of tuberculosis had been established in Massachusetts, Maine, Rhode Island, and New York. Since that time provision had been made and sanatoria had been opened or would open in the immediate future in New Jersey, Maryland, North Carolina, Ohio, Indiana, Michigan, Wisconsin, Minnesota, Iowa, Missouri, and Kentucky, while bills had been introduced into the legislatures and were being actively pushed in Delaware, Florida, Kansas, Alabama, Texas, and California. There was little doubt that this movement for State sanatoria would extend in the immediate future in such a way that every commonwealth in the Union would have its institutions for the exclusive care of this disease. Side by side with the growth of State sanatoria had gone the movement for the establishment of local sanatoria, which the National Association emphasized as an essential feature in the campaign. The growth of dispensary establishment had also been most striking, and particular attention to this phase of the care of the tuberculous was being paid in our larger cities. The importance of proper care of patients in their homes by trained nurses, in cooperation with dispensary treatment, was now being recognized in all of our cities. Since last May eighteen new tuberculosis dispensaries had been established in the United States. The increase in the number of cities requiring notification of cases of tuberculosis with the health authorities was also most encouraging. Of eighty-five cities with populations of over 48,000 from which reports were obtained, more than fifty now required the reporting of tuberculosis. One of the strongest stimuli which the National campaign had received was the executive order of President Roosevelt issued over a year ago appointing a commission to inquire regarding the conditions existing in government offices and workshops for the prevention of tuberculosis in such buildings. This order resulted in a report from the commission, and was followed by a second executive order, directing the head of each department in Washington to cause to be printed and transmitted to all Federal buildings under his control rules prepared by the commission to prevent the spread of tuberculosis in such places. Through the distribution of these rules, and their conspicuous posting in such build-

ings as the post-offices through the country, a publicity to the movement against tuberculosis had been given which could hardly be attained in any other way. Following the President's example, governors of certain States and mayors of cities had taken up the matter, and were issuing orders similar in purport with regard to public buildings under their control. Less tangible but equally important was the formal action taken by certain national bodies of influence. The National Federation of Women's Clubs had made the subject of tuberculosis one of its chief subjects of study and work, and through its State and local branches was cooperating with the National Association in its educational measures. The Young Men's Christian Associations, through their Physical Education Department, had also taken the matter up with vigor, and through their classes were accomplishing much in a group where the age made them particularly liable to the disease. The recognition of the importance of the work by educational bodies, teachers' institutes, etc., was a further guarantee of the ultimate success of the campaign. The great task was one of prevention, and this involved the observation of a proper hygiene by every individual, and care against infection through the sputum of careless consumptives. The spread of this doctrine was now so rapid and the enthusiasm in the anti-tuberculosis campaign was so great that the prospects of ultimate success in stamping out this greatest of scourges seemed more than promising.

AMERICAN MEDICAL ASSOCIATION.

Fifty-eighth Annual Session, Held at Atlantic City, June 3, 4, 5, 6, and 7, 1907.

(Special Report to the MEDICAL RECORD.)

(*Continued from Vol. 71, page 1013.*)

SECTION ON SURGERY AND ANATOMY.

Thursday, June 6—Third Day.

Symposium on Ileus.—Professor K. G. LENNANDER of Upsala, Sweden, presented this paper, which was read by the Secretary, Dr. Cushing. After long experimentation, the author had reached the conclusion that pain was not transmitted by the vagus, that in order to have this special sense an organ must be innervated by other nerves. In demonstration of this it was cited that the upper aspect of the liver was insensible, because it was not reached by the cerebrospinal nerves. The parietal peritoneum and its subserous layer was described as transmitting the pain sense very sharply and invariably. The visceral peritoneum, however, was not endowed with this sense. Even a mild degree of stretching of the mesentery caused distinct pain. The same was true of adhesions if they were connected to the parietes. If, however, they were not so connected but were interenteric in their nature, almost any amount of traction upon them would elicit no pain. Sensation of pain, according to the author's observation, increased to its maximum in the neighborhood of the foraman of Winslow. Some one had well said that pain varied inversely as one approached the pelvis. As to the pain of perforation, which all clinicians knew to be an easily demonstrable and very constant factor, it was believed to be due to the contents of the organ coming into contact with the parietal peritoneum. This was the cause of the early pain. As was known clinically, this usually wore away gradually, and the secondary pain, which was equally characteristic, was due to and in proportion to the degree of secondary inflammation. The pain of colic was not due to the pressure of nerves brought about by distention, because the entire wall of the gut might be entirely but slowly crushed with artery forceps without causing pain. This latter could only be induced by traction on the parts already referred to. In general, the author concluded that colicky pains, or pains of any character originating in the abdomen, could not come from parts supplied by the vagus and sympathetic either alone or in conjunction; that spinal nerves, such as were found in the parietal peritoneum, were the only nerves which conducted pain sense from the region; that stretching of attachments of any kind whatsoever to the parietes caused pain; that a spilling of the contents of the perforated organ was the cause of the primary pain of perforation; that the sensitiveness of the parietal peritoneum increased until the inflammatory processes progressed too far to permit of continued sensibility of the nerve endings.

Experimental Studies of Intestinal Obstruction.—Dr. R. D. MCCLURE of Baltimore read this paper. He said that in obstruction situated in the oral portion of the small gut the symptoms were well known to be entirely out of proportion to the mechanical severity of the lesion. For it was to be remembered that patients suffering from dynamic ileus situated in the upper portion of the jejunum often perished with very characteristic and fulminating symptoms within from forty to eighty hours, whereas the same type of obstruction situated in the aboral or low iliac portion of the small gut would give rise to an entirely different set of symptoms, and might not terminate in death for a length of time often exceeding a week. A number of explanations had been offered to explain these phenomena. Prominent among these were the so-called nervous theory and the absorptive theory. He recited a number of interesting experiments which had been performed at the Johns Hopkins Laboratory and which were directed toward the elucidation of these unknown conditions. Under perfect asepsis, observations were made every day after an obstruction had been produced by simple ligation of the gut. It was definitely shown that after seventy-two hours, although purple, the loop would contract. He spoke of the characteristic tapering of the dilatation and described the giving of pilocarpine and other drugs after the intestines had been floated in a water bath. As a rule, at autopsy of animals dying of mechanically produced jejunal ileus, the dilatation of the loop was marked. Smears of the loop contents showed a large quantity of bacteria to be present, often of new and bizarre forms. Many of these would grow upon the usual media, whereas a very large portion of them would not. This had rendered difficult the determination of this type of intestinal flora, a subject which was at present being pursued in the laboratory. In an attempt to determine the degree of toxicity of the material contained in the loop, efforts had been made to transplant the contents from one loop to another, but these had been so far unsuccessful. Their experiments seemed to justify the statement that bile and pancreatic juice had nothing to do with the etiology of death.

Physiological Observations on Experimentally Produced Ileus.—Dr. WALTER B. CANNON of Boston read this paper. He dwelt first on the physiology of the peristaltic wave, stating that it was due to the action of a coordinated mechanism which lay in Auerbach's plexus. He then detailed the potato-bismuth observations, by means of which his studies had been carried on. As in previous observations, the shadows had been measured and the total length computed. This gave a very accurate means of determining the amount of food passing to a given place. He then showed the tabulated results of the effect of various stimuli which in succession and in conjunction were applied to the animal. When ether was given the discharge from the stomach was slow. If, under ether, the testicle of a cat be crushed, an immediate retardation or cessation of this discharge would at once be noted. He and Dr. Murphy, his collaborator, then turned their attention to the elucidation of the question: Did this retardation come through the splanchnics? In another series, accordingly, the splanchnics were cut. One week later

the animals were subjected to the above operation under ether. The result showed an absolutely normal passage of food, and the conclusion was self-evident that the reflex inhibitory stimulation from the injury to the testicles must have reached the intestines through the splanchnic nerves. Again the authors directed their attention to the answering of another important question, viz., Was there a local source of inhibition? This was studied by the application of a variety of local traumata, such as drying, chilling, etc. These were found to have no effect. Manipulation, however, resulted immediately in marked depression of activity and in the holding up of the passage of food for hours. Whence the inhibition? Was it reflex through the splanchnic, or of local origin? If the latter and the splanchnics be cut, then logically the same result should be obtained as in previous findings. This, however, was found not to be the case, and the conclusion was self-evident that there must be a local disturbance of the mechanism which lay in the wall. These studies were not carried on for the purpose of answering questions of purely academic physiological interest, but were intended to have a direct bearing upon the treatment of human ileus. Attacked from the standpoint of drug therapy, if extrinsic, inhibition of the splanchnics should help; whereas, if local, obviously a drug affecting the local conditions in the canal should be employed. It was found that physostigmine was restricted positively to those conditions where failure of peristalsis was due to reflex inhibition through the splanchnics. Tincture of aloes, known to be one of the most potent stimulants of a local nature to the intestinal canal, as well as a manipulation of the gut itself, did not help at all. A very interesting observation about physostigmine was that if given early it was valueless, but if given one hour after operation an immediate discharge of food was observed to begin. The effect, however, was temporary. The conclusion was that there were two factors in causing the form of ileus under consideration and that every effort should be made to differentiate them.

The Symptoms and Diagnosis of Strangulation of the Intestines.—Dr. JOHN B. ROBERTS of Philadelphia read this paper. He said that there was a striking similarity between the symptoms of obstruction and those of strangulation, the first usually being an accompaniment of the latter. This obviously made differential diagnosis extremely difficult, rendering it possible indeed in none but the very earliest stages. Whatever might be the cause of strangulation, the end results were the same. At the initiation of the condition the pain might be localized or diffuse. He made it clear that secondary pain was always due to peritonitis. He further called attention to the fact that practitioners should bear in mind that an overdistended bowel never gave a tympanitic note, but one which could in a measure be likened to that obtained by percussion of certain parts of the chest. Of the urine and feces, he said no important data were to be gained, while a study of the blood, although revealing occasionally a well marked leucocytosis, could hardly be depended upon as an important aid in diagnosis. Rise of temperature suggested the onset of peritonitis, but this was not an invariable accompaniment of such rise. In chronic obstruction there was invariably no visible peristalsis, whereas this was present in the acute form. In closing he emphasized that if a diagnosis could not be made positively in from twenty-four to forty-eight hours, the abdomen should be opened and the contents inspected.

Postoperative Ileus.—Dr. FRANK MARTIN of Baltimore had communicated with the leading surgeons of the country and, according to their personal reports, had found that the percentage of postoperative ileus varied from 1-10 to 2 per cent. This showed that the condition was by no means a rare one. Among other interesting facts, he stated that a number of surgeons had reported cases of ileus developing after operations in which the peritoneal cavity was not opened. These, he said, were usually classed as belonging to the adynamic type. Ochsner had reported from his immense service at the Augustana Hospital of Chicago no cases whatsoever of postoperative ileus. This he ascribed to the method of treatment, which was routine practice at the Augustana, viz., starvation, combined with castor oil. He stated that no adequate classification of ileus had yet been made and referred at length to Wilm's well known work on the subject. He said that the mechanical, the septic, and the adynamic were the three most important types. As to diagnosis, he held this to be extremely difficult, and insisted that the symptoms must be studied at the very incipiency of the disorder, because their characteristic was to so change in type as to be valueless for diagnostic purposes. In the early stages a stiffening of the belly wall was generally absent. Symptoms of shock were of great moment. In closing he spoke of the frequency with which abdominal adhesions were disposed of by natural processes.

Dynamic Ileus.—Dr. JOHN C. MONROE of Moston said that ileus had too long been considered a disease in itself. This it was not, but rather a group of symptoms which in their incipiency were characteristic. He held that the term should be abolished. Antioperative or postoperative obstruction might be severe or might be simple. He believed distention to be generally due to a preexisting peritonitis, for it was rarely seen in uncomplicated obstruction. Pneumonia and nephritis were not uncommon accompaniments, particularly in the derivatives of the primary mid-gut, it was of the utmost importance to avoid all forms of traumata. Lavage of both ends of the alimentary canal were very important and the most efficacious mode of conservative treatment. Cathartics, of course, were universally known to be exceedingly dangerous. This was an excellent illustration of the fact that an increase of the condition established by nature were the means best directed for the treatment of the condition. When the gut was obstructed increase of peristalsis would destroy the natural protective barriers. This, of course, was true of toxic ileus, which should in the rarest cases only be operated upon, was made worse by a catharsis, was to be treated by rectal irrigation, and was best relieved by the copious use of morphine. This relieved the pain, quieted the bowels, and acted consequently as a cathartic. In conclusion he stated that the common, acute, and postoperative form of ileus was generally due to trauma inflicted at time of operation or else to slight local infection. These, he said, should be treated rather than the ileus.

Resection for the Relief of Intestinal Obstruction.—Dr. WILLIAM J. MAYO of Rochester said that the delay in affording suitable surgical intervention was in almost all cases the cause for the need of intestinal resection. This, in other words, usually arose from interference with the blood supply. It had been definitely shown by many observers that the condition of obstruction by its very interference with the resisting powers of the intestinal wall allowed of permeation of that wall both by germs and by toxins. He said that the evacuation of the contents oral to the obstruction was of the very greatest importance, and stated that many lives would be saved in this condition by a more liberal use of the stomach pump. There was something exceedingly poisonous in the contents of the loop, and if this material were driven through the intestinal canal instead of being washed out, preferably at time of operation, by its removal from the loop or occasionally after it had regurgitated into the stomach by gastric lavage, a very high mortality was certain to result. Because of the fact of certain specific changes in the wall of the gut, produced by these poisonous materials, it was necessary, in case resection were undertaken, to cut out a liberal amount of gut. He said the distended intestine should not be handled; that no pull should be made

upon the mesentery; that it was much better to make a double incision through the abdominal wall than to attempt to reach the intestine from a misplaced opening. He advised lateral anastomosis, and stated that the opening must be at least two inches long. Save for slight angulation, such an opening, if properly made, would leave no final imprint on the course of the intestine. This lateral anastomosis was to be used in acute cases only, and preferably in the small gut where the contents were fluid. End-to-end anastomosis was perferable in chronic cases and in the large intestine. In the ileocecal region anastomosis should always be lateral. If a button were used it should always be protected by four interrupted sutures. As to resecting the transverse colon, he said that in four cases out of five the middle colic artery was its sole blood supply. It should not be forgotten that the splenic flexure and descending colon were normally empty, constituting, as it were, simply a passageway from the transverse colon to the sigmoid. Resection here had better be made in three stages, because the complete final operation had a very high mortality. He emphasized the value of the upright position to get drainage away from the diaphragm, which the researches of Buxton and others had shown to be the great medium for the absorption of bacteria and their products. In addition to this, he urged free rectal irrigation to aid elimination and gastric lavage for the removal of poisonous materials which so frequently entered the stomach.

Dr. E. Wyllys Andrews of Chicago opened the discussion. He presented a new method of intestinal anastomosis. It combined the speed and safety of the McGraw ligature, but by the application of a simple device was opened immediately. A pair of cutting forceps with slender blades completed the opening. He gave a demonstration upon a piece of intestine and showed the admirable working of his instrument.

Dr. S. J. Meltzer of New York continued the discussion. He confined himself to a consideration of Lennander's paper, devoting particular attention to the sensitiveness of the intestine as to pain, to the question of presence of nerve fibers, and to Lennander's hypothesis, explaining the cause of abdominal pain. He said that in his experience the intestine of dogs were very sensitive to pain. He wondered if there could be a difference in the species. In rabbits, he said, the intestine was not sensitive to pain. Another observation which he made was that cocaine has the property to abolish pain, not only locally, but in distant parts. It also quieted the animal. Absence of pain, as recorded by Lennander, he thought might be due to this hitherto unrecognized property of cocaine. He believed that a disappearance of the pain was probably the first sign of appearance of shock. Inhibition was probably the cause of this. Simple laparotomy had unmistakable effect upon the peristalsis, motor activity often disappearing with the opening of the peritoneal cavity. This had even been observed when incisions were made elsewhere.

Dr. W. G. MacCallum of Baltimore paid high tribute to the value of Dr. Cannon's paper, and reported two observations which he had made which he believed supported Cannon's conclusions. At operation it was not uncommon to find no sign of obstruction, but to discover the oral portion of the intestinal canal to be in such a state of chronic contraction as to present the characteristics of an absolutely rigid tube. This was due to the inflammatory process in the wall. Another case which he had seen he thought illustrated Cannon's observations upon the splanchnic innervation. The patient presented all classic of signs of obstruction and was operated upon. No obstruction was found, but a dissecting aneurysm was discovered which was making tight pressure upon the splanchnics, because of infiltration of the region through which they passed. He said that there was no transmigration of bacteria through the intestinal wall, unless that wall were deprived of its natural resisting power owing to deficient nutrition.

Dr. J. W. Draper Maury of New York said that Dr. Cannon's paper had done much to explain many important and hitherto unknown phenomena of intestinal obstruction. He cited certain observations which had recently been made in a series of experiments conducted at the Surgical Research Laboratory of Columbia. In brief, these researches verified the fact that obstruction oral to the bile and pancreatic ducts was much more readily tolerated by an animal than obstruction just aboral to the ducts. All the work had been done in the relatively aseptic region of the primitive foregut. On account of the proofs recently adduced by several observers, notable among them being Meltzer, of the existence in the bile of two substances, one a violent spasmodic and of the fact that a colloidal suspension of the bile was necessary to prevent the action of this convulsant, the speaker believed it probable that the explanation of the fact that death took place so much more rapidly when obstruction was situated high up in the intestine than when placed near the ileocecal region lay in the fact that the obstruction interfered with the normal colloidal biliary suspension in a degree proportional in its nearness to the bile duct. Absolute proof of this hypothesis was as yet wanting, but experiments so far conducted appeared to support it. If further experimentation verified it, it might be easy to suggest the use of some therapeutic agent which would chemically or otherwise counteract the effect of the biliary poison.

Dr. James F. Mitchell of Washington reported two interesting cases which appeared to support Lennander's contentions. He chose two types of men from among those presented in his service, one an uneducated negro, and the other an educated white. By the simple use of a free amount of salt solution, to which no cocaine whatsoever had been added, he opened the abdomen of each. No general anesthetic whatsoever was employed. The demonstrations of pain complained of by each patient were the same. Each objected to the section of the anterior sheath of the rectus, and each complained of severe pain when the parietal peritoneum was clamped. No pain was caused by clamping the suspensory ligament of the liver, and when the colon was rubbed in each case there was no pain; but traction always caused pain. The parietal peritoneum was in each case exceedingly sensitive. In the case of the negro the intestine was clamped and rubbed. It caused no pain. Traction on the mesentery, however, caused much pain and nausea. The same thing was observed on traction of the appendix. The highest pulse rate was 70. This occurred when the skin was cut, when the peritoneum was cut, and when the mesentery was dragged on. The lowest pulse was sixty.

Dr. John D. Murphy of Chicago said that he regretted very much that there was still a great diversity of opinion as to the classification of ileus. It constituted a complex aggregation of symptoms, of which pain, nausea, vomiting, and meteorism were the most prominent. He said that bedside study was of the very greatest importance. He believed that a pain sense existed in the intestine. For the dynamic cause he said that morphia was by all odds the best form of treatment. For the adynamic the cause should be treated. For mechanical ileus the treatment obviously should be by mechanical means.

Dr. John B. Deaver of Philadelphia said that there were three types of obstruction to be observed at the bedside. He thought that too much importance should not be accorded to laboratory findings. The types referred to were postoperative, mechanical, and, lastly, those resulting from infection. Most cases of ileus had occurred after sepsis. The condition was but rarely seen in a clean belly. Gauze, in his opinion, was not at all a frequent factor in causing it, as some speakers had already observed, for

gauze was used very widely in his service. He believed that thorough cleansing of the alimentary canal before operation and very careful feeding after operation constituted the open sesame to the avoidance of ileus.

Dr. McGraw of Detroit emphasized the necessity of an early diagnosis of the condition. Mechanical obstruction, he said, had certain cardinal symptoms in its early stages which disappeared often before the diagnosis was made. Of these pain and vomiting with no distention, with no fever, with no tenderness, were the most important.

Dr. Morris H. Richardson of Boston said that in his experience it had been very difficult to tell what was the real condition and what was not in certain postoperative disturbances. Abdominal pain was the most important sign, particularly when accompanied by vomiting and distention. How to tell just what to do with these cases or how to successfully prognosticate the outcome of the conditions had as yet baffled him. There certainly did exist a picture which bore close clinical resemblance to the true ileus and from which patients always recovered, which was very hard to diagnose. He believed that such cases might present what he called a peritonism, viz., a low degree of peritoneal irritation without peritonitis, which would explain the resemblance of the symptoms and the difference of the outcome.

Dr. Hemmeter of Baltimore agreed with Dr. Meltzer that cessation of pain was an indication of shock.

Diabetes in Surgical Relations.—Dr. A. E. Halstead of Chicago said that traumatic glycosuria should be considered in its relation to the healing of fractures. In general it was better to wait until dietary and other measures had effected a removal or disappearance of sugar from the urine prior to the undertaking of operative procedures. He thought that if this precaution were taken diabetes should not constitute a serious contraindication to operation. The risk of infection of operative wounds in the diabetic subject was very great, but even this risk was much reduced if attention were given to minimizing the amount of sugar in the urine. He spoke of femoral glycosuria following trauma in surgical operations and dwelt upon its significance and relation to true diabetes. So important was it to get all pus infection out of a diabetic that operations for the drainage of pus cavities should be undertaken immediately and without waiting for any preoperative treatment. All operations upon a diabetic should be done with the greatest possible speed and with the least traumatism of the tissues. Young patients were naturally the poorest operative risks, the acid intoxication, which in them was present to a much greater degree than in older diabetics, proving a greater menace to life than the arterial sclerosis which is characteristic of the old. General anesthesia should always be avoided if possible. Ether was the anesthetic of choice, for it was well known that acetonuria developed in sixty-six per cent. of normal cases anesthetized by chloroform. Nitrous oxide was not free from danger. Bicarbonate of soda was indicated at all times to keep down the diacetic acid reaction of the urine.

Dr. Henry S. Stark of New York spoke of the difficulty encountered by the general practitioner in making the tests for diacetic acid and other substances which render treatment demanded. He thought it was questionable whether such a thing as diabetic gangrene existed. It merely followed an obliterating endarteritis and morphologically resembled gangrene occurring under other conditions.

Dr. Shelton Horsley of Richmond recited the history of a white man who had been shot in the head. The bullet struck the malar bone and broke in two, one fragment lodging in the soft tissue of the temporal fossa, the other entering the substance of the frontal bone. Glycosuria was observed to begin a very few hours after the injury. There was no sugar on the eighth day and patient recovered.

Dr. A. J. Ochsner of Chicago said that for fear of permitting the statement to go unchallenged that varying forms of gangrene did not materially differ, he wished to say that whatever their morphological resemblance might be there was a very positive difference in them clinically. In the diabetic form he had noticed without failure that if the sugar in the urine was disposed of by proper medical measure, the tendency to gangrene would disappear. This statement was based on the result of the study of 30,000 cases personally operated on by himself. The usual proportion of these patients had suffered from diabetic gangrene. He considered it demonstrated that gangrene due to age-endarteritis would yield to no form of treatment, whereas the diabetic form could be helped by treatment. He insisted that a surgeon should never attempt to care for a diabetic patient, for the proper treatment of this disease demanded constant medical care year in and year out.

Trigger Finger.—Dr. Robert F. Weir of New York read this paper. He said that the disorder was not common and was but little understood. It was first described in 1850 and first treated by operation in 1884. Since that date forty-two cases, all of which had been relieved by operation, had been collected. He had suffered from the affection himself, and Dr. Abbey had operated upon it for him. The cause of the condition lay in a disproportion between the size of the sheath and the tendon, the increase in size of the tendon being due either to traumatism, to tuberculosis, or to the development of neoplasm. It was more frequent in the left hand and usually occurred on the flexor tendons. It was probably not due to excessive muscular action, but to direct constant pressure upon the palm, such as would arise in certain occupations. He said that a local anesthetic was absolutely necessary, so that it could positively be determined when the tendon had been sufficiently relieved. It was noteworthy that all cases operated upon were cured, although in several instances no sign of the lesion had been found at operation.

Excision of the Rectum, Sigmoid, and Part of the Descending Colon with Implantation of the Colon into the Anus.—Dr. Edward Archibald of Montreal, Canada, read this paper. It was based upon a case of chronic ulcerative tuberculosis of the rectum and colon occurring in a young man and existing for three years. A left colostomy was done. This afforded a measure of relief and was kept open for more than a year without, however, effecting a cure. It caused so much trouble to the patient and the pain of the disease was so great that he insisted on the performance of a radical operation. The technique of this operation was the important part of the contribution. It consisted in the cutting of the mesosigmoid, or mesocolon, to a sufficient extent to obtain adequate mobilization to enable the splenic flexure of the colon to be brought down to the anus. The speaker showed a most instructive series of preparations from the cadaver, the arteries of which had been injected after the ligation of the vessels necessary to effect this mobilization. In all cases in which this ligation and injection was performed there was shown to be a full and adequate blood supply to the entire region mobilized. He discussed the feasibility of utilizing this technique for radical operation on malignant neoplasms of the rectum and lower sigmoid. The Kraske's operation was attended by a very high mortality, and the combined abdominal-perineal operation as advocated by Mayo, even in his skilled hands, had a dangerously high mortality rate. There were in the operations upon this region three important points to consider, viz., the mortality, the postoperative control of bowel contents, the permanence of cure. One chief advantage of the form of technique offered by the speaker lay in the fact that by its employment all glands could be removed. That this

was a matter of the highest importance was demonstrated by the fact that Kraske now combines his original operation with abdominal section. The objection to the Mayo operation lay in the fact that the artificial anus was always bad and further there was an immediate high mortality due to shock. The ideal operation was a complete removal of the bowel with its lymphatics and a subsequent fecal control through the natural channels.

Direct Transfusion of Blood.—Dr. GEORGE CRILE of Cleveland said that off and on this work had been done more or less for the past four centuries. Most of it, however, was accomplished very crudely. His paper was based partly upon conclusions derived from 225 operations upon animals and partly upon what he had observed as a result of the application of such experiments to human beings. The conclusion reached was that the vascular systems of normal individuals of the same species might be connected if this were done according to modern technique without harm to either individual. There should be no clotting if technique were properly executed. The blood lost by the donor was usually regained in about five days. All manner of experiments have been performed, blood having been emptied from one animal into another and again into a third and vice versa. No metabolic changes could be found resulting from these operations. No hemoglobin was found in the urine. Overtransfusion, such as would be obtained in using a disproportionately large donor, was a dangerous factor, for the right heart might readily become engorged and frothy sputum appear at the mouth. Liver and spleen might be ruptured. The blood pressure was raised by transfusion higher than by saline infusion, for blood is physiologically better than water. The employment of this method was particularly applicable to resuscitation after severe hemorrhage, either accidental or induced. Induced hemorrhage followed by transfusion in cases of strychnine poison and after double nephrectomy did no good. It was curative of illuminating gas poisoning and of surgical shock. In this condition death was due to circulatory failure of vasomotor center. As a preventive of shock transfusion was probably the most important means of control at our hands. Animals physiologically overtransfused could not be killed by shock alone. In pernicious anemia and in leukemia there was no improvement. In cases of chronic suppuration there was a temporary improvement in vitality. In tuberculosis there was no gain. He referred to the immunity which could be contributed to certain animals in their ability to absorb tumors of sarcomatous type. In hemorrhage arising from a failure of the blood to clot the treatment by transfusion seemed to offer great promise.

Dr. BEEBE of New York said that it was a question what was the cause of immunity in animals. He exhibited charts which showed most beautifully the regression of tumors following transfusion.

Dr. LOWER of Cleveland spoke of the technique usually employed by Dr. Crile and his associates in practising human transfusion. He said that the radial artery was usually used; that the work was done under local anesthesia. Unless a large enough vessel were used there might be sufficient contraction to stop the blood stream. By the judicious use of local anesthesia one was generally able to accomplish the operation almost without the patient's knowing it.

Paraffin Injection Treatment of Inguinal Hernia.—Dr. M. L. HARRIS of Chicago read this paper. He said that this pernicious method had been introduced fifty years ago and been used extensively throughout the West by itinerant quacks. It had universally ben proven not to be permanent, and many accidents had followed its use. As to the position of the paraffin, he had found that in some cases it had been injected directly into the cord, in some into the tissues of the external oblique. He thought that it should be condemned as unsuccessful and unsurgical.

Dr. DEGARMO of New York agreed with the author of the paper.

Dr. ROBERTS of Philadelphia thought that there might possibly be occasions upon which the injection treatment might be useful.

Dr. BEVAN said that he had seen two cases of neoplasm occur after paraffin injections. These growths had been dissected out and under the microscope presented the gross appearance of Swiss cheese. The clinical behavior was that of paraffin, and it might be concluded that this condition may be produced by paraffin injection.

Pseudoarthrosis.—Professor SCHMIEDEN of Bonn read this paper. He said that in Bier's clinic a great many experiments had been made relating to the value of the injection of blood in cases of failure of bone union. He said that reaction was particularly marked if heterogeneous injections of blood were made into the part. The inflammatory reaction of simple fracture, he said, might be studied from this standpoint, and the bone deposit be shown to be the direct outcome of the hemorrhage at the site of break. On account of these facts Bier had for long held that failure to unite might be due to lack of a suitable amount of blood. It was therefore the hemorrhage which resulted from it and not the curettage which helped, when the ends of bones were scraped for non-union. Pseudoarthrosis was usually due to a bad condition of the patient rather than to bad treatment because of the generally good modern technique. Injection of blood was much better than that of other irritants. The technique was simple. It consisted in a puncture of a vein and the removal in a very strong syringe of from thirty to forty c.c. The injection was made between the fractured ends and around them. The blood should be introduced before coagulation could take place. A better result was obtained by taking blood from a different individual. One such treatment might suffice, or it might have to be repeated six times. He concluded that Bier's views were correct that the blood was the material which started bone growth.

Dr. DAWBARN of New York said that quacks had used a concoction for injection made of white oak bark and glycerin. This resulted in the formation of a glycerite of tannin. Callus was nature's glue, and it became whatever tissue it was placed in contact with. He spoke of the necessity of making a proper differential diagnosis.

Technique of Operation for Cancer of the Breast.—Dr. MILES F. PORTER of Indiana said that the principal object that we sought for was to secure as rapid and perfect recovery as possible. The incision advised for most cases followed the lower border of pectoralis major with oval about the breast. Vertical incisions in the axilla and those of acute angles were to be avoided. He said that a great deal more tension could be put on the skin of these parts than was usually supposed, and urged that skin grafting was in most cases unnecessary. He advised the employment of buried sutures in the axilla.

Dr. W. L. RODMAN of Philadelphia agreed with the speaker as to the desirability of free removal of the skin. The greatest danger to the patient, he said, had been a tendency not to cut away enough. The advantages of skin grafting freed the operator from the fear of too much skin removal. All efforts were to be made to avoid the formation of a bridle scar, and for this reason he advised not incising too low down on the arm. He thought that all muscles should be removed, and recent researches showed the truth of Halstead's stand, proving the desirability of removing all supraclavicular glands if the new growth were situated in the upper quadrant of the breast. He believed that it was just as well to drain.

Friday, June 7—Fourth Day.

Experimental Pathology and Surgical Treatment of Erysipelas.—Dr. ERNEST LAPLACE of Philadelphia read this paper. He spoke of the important results which had

been derived from the addition of tartaric acid to a solution of bichloride. It altered the soil and also altered the virulence of the germs. He considered that his experimental demonstration had shown the varying virulence of the streptococcus, the more alkaline the medium, the more violent the erysipelas. The well known lack of immunity from second attack agreed with the observation that opsonins disappeared quickly from the organism. He believed that scarification with ice cold applications of bichloride acid with tartaric acid would successfully limit most cases of erysipelas.

Dr. Ochsner of Chicago said that if the streptococcus should be changed in virulence this paper was to be regarded as reporting a great step in advance. He believed that practically it was a very important point to treat the disease in its very incipiency. If this were not done no form of treatment would control it. He recited the history of the epidemics observed in the German prisons where they had years ago observed that alcohol, if used in the very early stages, was curative. If there was uniformity in morphological changes in the germ, it was a remarkable observation. It was well known that there were mild types of infection.

Dr. Laplace in closing said that germs certainly do change in virulence. He applied the argument to the appendix, and said that in it alone there was presented an example of old-time hospital gangrene.

A Case of Benign Melanosis.—Dr. J. Clark Stewart of Minneapolis said that melanotic conditions, the result of dissemination of melanoid sarcomata, were relatively common, but that so far as was known benign conditions resulting in the staining of the milk, sweat, urine, etc., had not yet been observed in the human being. He reported such a case occurring in a woman who, fifteen years ago, when she was thirty-two years of age, was operated on for ovarian cyst. When the abdomen was opened the entire cavity was found to be lined with small melanotic daughter cysts, which at the time were pronounced to be melano-sarcomatous in origin. Examination, however, showed that this statement was erroneous, and clinically the diagnosis of a benign condition was established by the fact that the woman improved greatly under electrical treatment for the growth. Pregnancy appeared to start the condition of melanosis into great activity. The supposition was that the original cyst was either a dermoid or a parovarian cyst which had undergone degeneration. The cyst might have ruptured and have planted many smaller cysts in the peritoneum.

Anatomy of the Palate, Normal and Cleft.—Dr. Truman H. Brophy of Chicago, in this paper, affirmed his well known utterances on this subject and said that a continued study of the subject had led him to an even more definite conclusion of the truth of the finding that there was no actual loss of tissue in cases of cleft palate; that the normal amount of tissue was there, but that it was simply displaced laterally. There was a failure of union of the maxillary bones at the median line. He accounted for this failure in one of two ways. The predisposing cause was heredity; the exciting cause the application of force in the growth of the embryo. The mandible brings pressure which tends to separate the gap, as does also the tongue and the flexed position of the head. He concluded that the treatment consisted in a closing together of the bones within three months after birth, the soft palate being repaired later and the lips last.

Hepatic Abscess, Etiology, and Treatment.—Dr. John McDill of Manila read this paper. He said that this was the most important characteristic disease of the tropics. For some reason, owing probably to the character of their food, the Chinese were almost exempt. The whites furnished about ninety per cent. of the cases of abscess. He considered alcoholic excess to be the most important predisposing cause. The liver, he said, was normally a septic vault. The double blood supply helped to rid it of infection, and obviously anything interfering with this would tend to the formation of abscess. He referred to Musgrave's observations and said that he had finished his studies on the ameba. He said that diarrhea was not always present, even though amebas might be present in the intestines. The right lobe of the liver was generally infected. There was no relation of the abscess to intestinal ulcer. Death was due to admixed bacteria which killed by sepsis. The fever was irregular, if present. It might be entirely absent. Pain rarely appeared until the abscess reached the surface of the liver. Leucocytosis was constant. Primary intestinal disease, however, might give from fifteen to twenty thousand. This cause should be carefully eliminated by irrigation. A dry irritating cough meant that perforation into the lung was imminent. Exploration with the hollow needle was dangerous. He advised the transpleural route, describing a flap operation by which the tenth and ninth ribs were resected, and the gutter which had contained them closed. This loose wall was then pressed down and an opening made at the eleventh rib. The edges were clamped to prevent pneumothorax. This was then sewed up and abscess opened. He concluded that abscesses always contained the ameba; that early recognition could be made by finding them in the gut; that solitary abscesses were most frequent; that the best route was transpleural; that early operation resulted in ninety per cent. of recovery.

Dr. Powers of Denver said that probably no one present had seen anything like the number of cases which Dr. McGill had had the opportunity to study.

Dr. Cushing of Baltimore spoke of the new Manila School of Medicine and its importance to Continental United States. He asked whether it had been definitely decided that Shiga's bacillus was the primary invader or whether it was secondary to the ameba. He considered the transpleural route as described by the speaker as offering the most practical mode of access to the liver.

Dr. McGill in closing said he believed that most abscesses, if multiple, would coalesce and discharge through the primary opening. Amebas he believed to h every universal in their distribution, but they seemed to be more pathogenic in the tropics. The condition of the gut must be favorable to the development of the pathogenic form. He thought that everywhere routine examination of the stool should be made, and stated that one drop of the third or fourth movement after the giving of a large dose of salts was the most certain way of finding the parasites.

The Management of Dislocation at the Shoulder Joint, Complicated by Fracture of Neck of the Humerus.—Dr. H. A. Royster of North Carolina read this paper. He said that these fractures were more common than generally believed, and showed that the only rational treatment consisted in immediately cutting down over the joint and reducing both the fracture and dislocation at once.

Dr. Kocher of Berne said that an exact diagnosis of the character of the dislocation should be made before his father's method of reducing it should be employed. It did not apply to the correction of every type and might readily give a spiral fracture of the surgical neck.

The Results of the Operative Treatment of Deformed Fractures.—Dr. Carl Beck of New York, in this paper, emphasized the necessity of the careful routine employment of the *x*-rays as an aid to diagnosis and to treatment. He said that if this principle were followed out cases of nonunion would be very rare. He showed a great many interesting photographs demonstrating his paper.

Officers.—Dr. Rudolph Matas of New Orleans was elected *Chairman*, and Dr. Willard Bartlett of St. Louis, *Secretary*.

State Medical Licensing Boards.

STATE MEDICAL EXAMINING BOARD OF WASHINGTON.*

SPOKANE.

January 2, 3, and 4, 1907.

SURGERY.

1. Give the differential diagnosis between dislocation of the head of the femur and a fracture of the neck. Describe the treatment of the latter.
2. Give a summary of the treatment of fracture of the patella by the non-operative method.
3. Give the treatment of delayed union in ununited fracture.
4. Describe the different varieties of hernia, and describe one operation for inguinal hernia.
5. Name the different varieties of aneurysm, and the method of treatment of aneurysm in general.
6. Give the symptoms, diagnosis, and treatment of intestinal obstruction.
7. Give the symptoms, diagnosis, and treatment of chronic tuberculosis of the kidney.
8. Give the treatment of shock resulting from hemorrhage.
9. Give the contraindications for the employment of ether and chloroform.
10. Describe and give treatment of an infection under the palmar fascia.

PREVENTIVE MEDICINE AND MEDICAL JURISPRUDENCE.

1. Differentiate between idiocy and lunacy.
2. How would you determine that a full-term dead babe was born alive or still-born?
3. Give a detail account for an examination of a body from the standpoint of the coroner in charge.
4. How do you determine that an incised wound was inflicted by a blunt or a sharp instrument?
5. What constitutes expert testimony?
6. How long after recovery would you keep in quarantine a case of (*a*) diphtheria, (*b*) scarlet fever, (*c*) smallpox?
7. Name the portals of entry of tubercular infection.
8. State the best means of disinfecting sputum.
9. Describe the difference between contagion and infection.
10. (*a*) What are the effects of breathing impure air? (*b*) How many cubic feet per person should be allowed in a room for continued occupancy, and in a sleeping-room.

PRACTICE OF MEDICINE AND DISEASES OF CHILDREN.

1. How would you differentiate between chronic gastritis and carcinoma of the stomach?
2. Define constipation and give its causes, symptoms, effects, and non-medicinal treatment.
3. What is vertigo and its different varieties? Give the diagnosis and treatment of one.
4. Give the etiology, symptoms, and treatment of hydrothorax.
5. Give causes, symptoms, diagnosis, and treatment of myxedema.
6. Describe an attack of angina pectoris. Give its etiology, diagnosis, and prognosis.
7. What is asthma? Give its causes and symptoms.
8. Differentiate between hypertrophy and dilatation of the heart, and outline treatment for each.
9. What are the causes, symptoms, and effects of adenoids?
10. Describe an attack of enterocolitis in a child. Give its etiology and dietetics.

*It is proposed in this department to publish from time to time the examination papers of the various State Boards, in order that a candidate may become familiar with the character of the examination and so in some measure free himself in advance from the nervousness and dread which the unknown inspires. In furtherance of the same object answers to some of the questions will be published in order to show the candidate what the examiners expect of him. Not all the questions of all the papers will be so treated, for the answers to many, especially in the anatomical papers, are obvious or can be found in the Index of any textbook on the subject; the answers to other questions, especially in the surgical papers, must sometimes be omitted because of the space they would demand. The candidate for a medical license will not find in these answers a short and easy road to success in the examination, for he is not likely to meet the same questions in the papers placed before him by the examiners. The object of publishing the questions and answers is only, as noted above, to acquaint the candidate with the general character of these examinations and to inspire him with confidence in the result of his trial.

11. What are the etiology and symptoms of alopecia areata? How is it distinguished from ringworm?
12. Describe an attack of pertussis. Give its etiology, pathology, complications, and sequelæ.
13. What are the etiology, symptoms, and treatment of stomatomycosis?
14. Contrast ordinary dairy milk with human milk, and give a brief description of the essentials for the production of pure dairy milk.
15. Give symptoms and course, with differentiation, prognosis, and treatment of tubercular meningitis in a child.

OBSTETRICS AND DISEASES OF WOMEN.

1. Define presentation and position. Give three examples of each. Which of the latter is the most common?
2. Which is the greatest diameter of the female pelvis, also that of the fetal head? Give the mechanism of rotation of the latter during parturition in the first position.
3. At what time of gestation is the placenta formed? How would you treat an inevitable abortion subsequent to its formation?
4. In a difficult labor, upon what would you base your decision as to whether Cesarean section or the application of forceps would be the proper procedure?
5. What is placenta prævia? Name the different attachments of the placenta in the same. Give the method of management.
6. Give the symptoms and diagnosis of ectopic gestation.
7. Give the common causes of subinvolution of the uterus and the treatment of each.
8. Define metrorrhagia. Name two of its most common causes prior to the menopause. What would you suspect should it occur subsequent to the same? How would you verify your suspicion?
9. Give your treatment of a recent attack of specific vaginitis. Name two of its most common sequelæ.
10. Give two indications for hysterectomy. Which do you prefer, vaginal or abdominal? State upon what ground you would base your preference.

CHEMISTRY AND TOXICOLOGY.

1. What is an antidote to arsenic? What effect has arsenic on the gastrointestinal canal? What effect has it on the nervous system? In arsenic workers, what local condition may be found upon the hands?
2. What is an antidote to carbolic acid? What combination is formed by its administration? How would you make a diagnosis of carbolic-acid poisoning before death?
3. Enumerate the symptoms of chronic lead-poisoning and give the treatment.
4. Give the treatment of phosphorus poisoning.
5. What are the symptoms of nitrate of silver poisoning and what are the antidotes?
6. Complete the following formulæ: $Zn+H_2SO_4=$? and $BaO_2+2HCl=$?
7. What is an atom and what is a molecule?
8. What are isomeric compounds?
9. Describe the method of detecting uric acid by HNO_3.
10. Describe in detail a method of the quantitative estimation of sugar in urine.

ANATOMY AND PHYSIOLOGY.

1. Name in order the branches of the arch of the aorta.
2. Give the origin, course, and termination of the thoracic duct.
3. Describe the occipital bone and name the structures passing through the foramen magnum.
4. (*a*) What tendons form the inner hamstring? (*b*) The outer hamstring?
5. Describe a lumbar vertebra. In what points does it differ from a dorsal vertebra?
6. Describe the diaphragm. Mention the openings formed by it, and tell what structures pass through each. Give its nerve supply.
7. Describe the circle of Willis, and name the arteries forming it.
8. What are attachments of Poupart's ligament? How is it formed? Give its surgical significance.
9. How is the venous blood current maintained? What arteries carry venous blood?
10. Describe the normal heart sounds. Give causes which produce each.
11. Give the daily amount, composition, and functions of the bile.
12. What part does saliva take in digestion? What is its ferment? Name and give the physiology of the nerve supply.
13. Name and give the function of the various glands of the small intestines.
14. Give the physiology of visual accommodation to light and distance.

15. What is the physiology of blood formation?

HISTOLOGY, PATHOLOGY, AND BACTERIOLOGY.

1. Describe a sebaceous gland.
2. Name the layers of the mucous membrane, and give the locations where it is found.
3. Describe the cross-section of an artery.
4. Describe the iris.
5. Describe a peptic ulcer of the stomach.
6. Give the pathology of the blood in pernicious anemia.
7. Name the chief differential points between carcinoma and sarcoma.
8. Describe a method for staining tubercle bacilli.
9. Describe methods of culture of the diphtheria bacillus.
10. What is the Widal's reaction?

NERVOUS DISEASES AND DISEASES OF THE EYE AND EAR.

1. Give diagnosis and treatment of migraine.
2. What is tic douloureux? Outline treatment.
3. Mention etiology, symptoms and treatment of sciatica.
4. Describe a case of progresive bulbar paralysis.
5. Briefly describe a case of general paresis.
6. Define: hordeolum, chalazion, ectropion, entropion, ptosis, astigmatism and myopia.
7. Give symptoms and treatment of purulent conjunctivitis.
8. Give diagnosis and treatment of mastoiditis.
9. Describe and give the treatment of pterygium.
10. Give the three most common causes of otitis media.

MATERIA MEDICA AND THERAPEUTICS.

1. Define narcotics, anesthetics and sedatives. Give an example of each.
2. Define diuretics and diaphoretics. Give three examples of each.
3. Give the therapy of phosphorus.
4. Give the physiological action of opium and name its alkaloids.
5. Name the drugs you would exhibit in pneumonia, acute interstitial nephritis, and rheumatism.
6. Mention three heart stimulants. Give the adult dose of each.
7. Write a prescription for acute bronchitis, chronic constipation and acute cystitis.
8. Classify the following drugs: aconite, atropia, pilocarpine, ergot, elaterium and manganese.
9. Name four hypnotics and give the adult dose of each. Name four emetics and give the dose of each.
10. Define an alkaloid and give an example of the same. Define serum therapy. Mention three serums, the indications for their use and state the dose of each.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

STATE MEDICAL EXAMINING BOARD OF WASHINGTON. SPOKANE.

January 2, 3, and 4, 1907.

SURGERY.

1. In fracture of the neck of the femur, the head of the femur will be found in the acetabulum; in dislocation, the acetabulum will be empty, and the head of the femur will be found elsewhere, *e.g.* on the dorsum of the ilium. In the fracture, crepitus *may* be elicited; in the dislocation, never. In the dislocation, there is inversion and a fixed position of the limb, both of which are absent in fracture.

2. The knee is disinfected, then covered with antiseptic gauze, and firmly bandaged. The leg is extended on the thigh, the thigh flexed on the abdomen, a posterior splint is applied, and the foot is supported. In two or three days the bandages may be reapplied if the parts are in good condition, and a plaster-of-Paris dressing put on. The patient is then allowed to walk about; the plaster-of-Paris dressing remains on for about three weeks.

3. "When delayed union exists, seek for a cause and remove it, treating constitutionally if required, and thoroughly immobilizing the parts by plaster. Orthopedic splints may be of value. Use of the limb while splinted, percussion over the fracture, and rubbing the fragments together, thus in each case producing irritation, have all been recommended. Blistering the skin with iodine or firing it has been employed. If the case be very long delayed, forcibly separate the fragments and put up in plaster as a fresh break. If these means fail, irritate by subcutaneous drilling or scraping, or, better, by laying open the parts and then drilling and scraping at many places." (Da Costa's *Surgery.*)

5. The different varieties of aneurysm are: True; false; fusiform; sacculated; dissecting; arteriovenous, of which there are two varieties, varicose aneurysm and aneurysmal varix; cirsoid, and aneurysm by anastomosis.

9. The following contraindications for ether and chloroform are from Hare's *Practical Therapeutics:* "*Ether* should not be used by inhalation in bronchitis or acute nephritis, because of its irritant properties; in peritonitis or gastritis, because it is apt to induce vomiting; in aneurysm or in the presence of marked vascular atheroma, because it may rupture a blood-vessel by raising arterial pressure; nor in diabetes, lest it produce diabetic coma; and if anemia is present and an examination of the blood shows that the hemoglobin is below 50 per cent., the use of the drug should be avoided if possible.

"*Chloroform* is not to be used in cases of fatty heart or dilatation of the heart, in those with a known idiosyncrasy, nor in the so-called lymphatic persons with overgrowth of lymphoid tissues, as, for example, adenoids. In the latter case it is particularly apt to cause sudden death. In valvular disease of the heart chloroform may be used with caution, although ether is preferable. Given a case of valvular disease that must be subjected to operation, the chances are bettered with an anesthetic than without it, as the pain and mental shock are worse for the heart than is the anesthetic."

PREVENTIVE MEDICINE AND MEDICAL JURISPRUDENCE.

1. "Idiocy differs from other states of insanity in the fact that it is marked by a congenital deficiency of the mental faculties. There is not here a perversion or a loss of what has once been acquired, but a state in which, from defective structure of the brain, the individual has never been able to acquire any degree of intellectual power to fit him for his social position. It commences with life and continues through it." (Taylor's *Medical Jurisprudence.*)

4. A wound inflicted by a blunt instrument will have somewhat of the appearance of a contused wound; the edges will not be so clean cut, and the surrounding tissues will be more or less bruised.

5. In expert testimony the witness may give his *opinion* on facts or supposed facts as noted by himself or asserted by others. *Theoretically*, this can only be done by those perfectly familiar with the subject in question: but *practically* any (or almost any) physician with a license to practice is accepted as an expert witness.

6. (a) *Diphtheria:* till the patient is free from all signs of congestion or rhinitis, and continued bacteriological examination is persistently negative.

(b) *Scarlet fever:* till the patient is quite free from sore throat or discharges of any kind, and the desquamation has entirely disappeared; generally six to eight weeks.

(c) *Smallpox:* till all crusts or scabs have entirely disappeared.

7. The portals of entry of tubercular infection are: the respiratory tract, the alimentary tract, the skin, the mucous surfaces. It may be hereditary.

8. "In pneumonia and pulmonary tuberculosis, the sputum should be received in spit-cups partly filled with disinfectant solution, and kept covered when not in actual use. It may be treated with 5 per cent. of carbolic acid, or about 5 per cent. of any of the cresol compounds, or 1 per cent. of formaldehyde. Milk of lime and chlorinated lime are also efficient. Corrosive sublimate is very uncertain. By reason of its consistency and adhesive properties, sputum is one of the most difficult materials to sterilize." (Harrington's *Practical Hygiene.*)

9. *Infectious* diseases are such as are due to the presence of bacteria.

Contagious diseases are such as can be communicated by contact from a person who is infected to a healthy person.

10. (a) The skin becomes pale, there are gastric disturbances, general muscular weakness, mental impairment, and lowered vitality, resulting in the taking of various diseases.

(b) In a room for continued occupancy each person should be allowed 3,000 cubic feet of fresh air per hour, or at least 1,000 cubic feet of space with ample and adequate facilities for ventilation. In a sleeping room occupied by several people each person should have at least 750 cubic feet of space, with proper ventilation. A sleeping room occupied by one person only should have from 1,200 to 1,800 cubic feet of space.

PRACTICE OF MEDICINE AND DISEASES OF CHILDREN.

1. *Chronic gastritis* is generally caused by indiscretions in diet, or by mental worry; it may occur at any time of life, and is characterized by pain in the epigastric region which generally comes on after eating; there is apt to be morning vomiting, the vomitus consisting of mucus with undigested particles of food; there is seldom hemorrhage; the stomach may be enlarged, and examination of the gas-

tric contents shows free HCl diminished or absent, and the digestive ferments diminished.

Carcinoma of the stomach does not usually occur before forty years of age, is more common in males, the pain is localized and constant, vomiting is copious and occurs some time after eating; the vomitus contains "coffee ground" material; hemorrhages are common; a tumor may be palpated, and examination of the gastric contents shows absence of free HCl and presence of lactic acid; severe anemia and cachexia are also present.

3. *Vertigo* is a disturbance of the sense of equilibrium, a condition in which the patient or objects surrounding him appear to be in a state of rotation or oscillation. It is not a disease; but is a symptom of many pathological conditions.

The chief *varieties* are: (1) auditory, or labyrinthine, also called Menière's disease; (2) cerebral; (3) gastric; (4) toxic; (5) senile; (6) hysterical; (7) essential.

9. Adenoids a. *Causes:* The real cause is unknown, but the condition is generally observed in childhood; heredity is also supposed to be a factor; males are more frequently affected than females; malnutrition and scrofula seem to be causative factors; the condition is often associated with enlarged tonsils, enlarged cervical glands, hypertrophy of the nasal mucous membrane, deviations of the septum, spurs; it often follows some of the acute infectious diseases.

Symptoms: Mouth-breathing; snoring; open-mouth; a vacant, dull expression of the face; modification of the voice (nasal twang), with inability to pronounce certain letters.

Effects: Earache and other ear affections; mental deficiency; frequent attacks of coryza; nose-bleed; stunted growth; convulsions, laryngismus stridulus, and various other neuroses may also be noticed.

11. Alopecia areata. *Etiology:* The real cause is unknown; it has been regarded as a neurosis; as due to parasites; or as the result of malnutrition of the hair.

Symptoms: There are circumscribed round or oval patches of baldness, which may appear suddenly or gradually, generally in early adult life; the scalp appears unchanged or may be pale or hyperemic; there are no scales; occasionally the eyebrows or beard are involved.

It is distinguished from *Ringworm,* in that the latter is rare in adults, is characterized by scales in which are broken off stumps of hairs with split ends, and a microscopical examination shows the presence of the tricophyton fungus in ringworm.

13. Stomatomycosis is *caused* by a vegetable parasite, the oïdium albicans. The *symptoms* are redness, either general or in patches; swelling of lips, gums, cheek, and tongue; fetid breath; dribbling of saliva, or the mouth is dry; tenderness, and difficulty in eating. *Treatment* consists in cleanliness, antiseptic mouth washes, tonics, stimulants, and good general hygiene.

OBSTETRICS AND DISEASES OF WOMEN.

1. By *Presentation* is meant the part of the fetus which presents at the pelvic brim; examples—vertex, breech, face, By *Position* is meant the relation between a point on the fetus and a point on the maternal pelvis; examples, in a vertex presentation the positions may be (1) left occipito-anterior, (2) right occipito-posterior, (3) right occipito-anterior, (4) left occipito-posterior. The left occipito-anterior position of the vertex presentation is the most common.

2. The greatest diameters of the female pelvis are the transverse at the brim and the antero-posterior at the outlet; each of which is five inches.

The greatest diameter of the fetal head is the occipito-mental, which is five and a half inches.

3. "The placenta is formed by the union of the chorion frondosum and the decidua serotina, and therefore is composed of fetal and maternal tissues. In the third or fourth month of pregnancy it constitutes a distinct structure, although its site is indicated at a much earlier period by the increased thickness of the chorion at that point." (Williams' *Obstetrics.*)

6. "When extrauterine pregnancy exists there are: (1) The general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterility. Nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood, and with pelvic pain coincident with the above symptoms of pregnancy. Pains are often very severe, with marked tenderness within the pelvis. Such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating. This tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the size of two fists. (4) The os uteri is patulous; the uterus is displaced, but is slightly enlarged and empty. (5) Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua, in part or whole. Nos. 1 and 2 are *presumptive signs;* Nos. 3 and 4 are *probable signs;* Nos. 5 and 6 *are positive signs.*" (*American Text-Book of Obstetrics.*)

7. Subinvolution of the uterus is commonly caused by: Lacerations of the cervix; absorption of septic products; mismanagement of the convalescent stage of the puerperium, chiefly too early rising; tedious labors; misplacement of the uterus; retained clots or membranes; tumors of the uterus.

8. *Metrorrhagia* is a uterine hemorrhage independent of menstruation.

Two of its most common causes prior to the menopause are uterine displacements and tumors (chiefly fibroids and polypi).

Occurring subsequent to the menopause, cancer would be suspected.

This suspicion would be verified by a microscopic examination of a piece of tissue excised from the cervix.

10. Two indications for hysterectomy: Carcinoma and fibroids.

As to preference between the vaginal and abdominal routes, the following is taken from Garrigues' *Gynecology*: "If the vaginal route is available, it should be preferred, because it entails much less shock, requires a simple after-treatment, does not leave any visible cicatrix, predisposes less to hernia, and allows the patient to resume work in shorter time. On the other hand, the vaginal route is more difficult on account of the limited space. Hemorrhage is more troublesome to check, adhesions are harder to separate, and the bladder and intestine more exposed to injury and less accessible for repair. The pelvic cavity cannot be seen so well and the abdominal not at all. If tissue is left to mortify, it emits an offensive odor."

CHEMISTRY AND TOXICOLOGY.

1. Antidote for arsenic is freshly prepared ferric hydroxide. Arsenic acts as an irritant on the gastrointestinal canal and then causes inflammation.

On the nervous system it probably acts as a stimulant, if given in medicinal doses; in toxic doses it may cause paralysis. The local condition that may be found upon the hands of arsenic workers is as follows: If the epidermis is unbroken an eruption may appear, if the epidermis is broken the arsenic has a caustic and destructive effect; ulceration around the nails and shedding of the nails may also occur.

2. The chemical antidotes to carbolic acid are the soluble sulphates, such as magnesium or sodium sulphate. With the carbolic acid these salts form insoluble sulphocarbolates. Before death carbolic acid poisoning can be diagnosed by the hoarseness of the voice, in addition to all the other signs of corrosion, such as eschars on mucous membrane of mouth, vomiting, purging, abdominal pain, cold, perspiration, pinched and anxious face, collapse, etc.

3. The *symptoms* of chronic lead poisoning are: Wrist drop, severe colic around the umbilicus, constipation, feces clay colored, blue line on the gums at the junction with the teeth.

The treatment is first to remove the cause; then administer a purge of jalap and calomel combined with opium; iodide of potassium should also be given to help in the elimination of the lead.

4. The treatment of phosphorus poisoning is to administer first an emetic, then old French oil of turpentine, or solution of potassium permanganate, and avoid giving any oils or fat with the food.

5. The *symptoms* of nitrate of silver poisoning are: "Almost immediately after the ingestion of a poisonous dose of nitrate of silver violent pain in the belly, with vomiting and purging, comes on. At the same time evidences of widespread gastroenteritis develop. The abdominal walls are knotted and hard, and perhaps scaphoid. The face is anxious and livid and covered with a sweat When the vomiting occurs the ejecta are seen to be brown or blackish, or even white and curdy. The lips are stained white, but they rapidly become brown, then black. In some cases the nervous symptoms are severe and convulsions with delirium may occur. The convulsions are epileptiform. Death ensues either from gastroenteritis or from centric respiratory failure, accompanied by a profuse exudation of liquid mucus into the bronchial tubes.

"The *treatment* consists in the use of common salt, which is the chemical antidote, the employment of opium and oils to allay irritation, and in the ingestion of large draughts of milk and of soap and water for the purpose of diluting the poison and protecting the mucous membranes of the esophagus and stomach from the action of the irritant.

The bodily heat must be maintained." (Hare's *Therapeutics.*)

6. $Zn+H_2SO_4=ZnSO_4+H_2$.

$BaO_2+2HCl=BaCl+H_2O_2$.

7. An *atom* is the smallest portion of an element that can enter into a chemical reaction, or that can enter into the composition of a molecule.

A *molecule* is the smallest quantity of any substance that can exist in a free state.

8. *Isomeric compounds* are compounds which, while differing in properties, possess the same percentage composition.

9. Moisten the substance with HNO_3 and evaporate; then let it cool, and add a little NH_4HO; a brilliant red color is produced.

10. Method for the *quantitative estimation of sugar in urine: "Fehling's method.*—The solution is made as follows:

I. Dissolve cupric sulphate	51.98 gm.
in water to	500.00 c.c.
II. Dissolve Rochelle salt	259.9 gm.

in sodium hydroxide soln. sp. gr. 1.12 to 1,000 c.c. (Piffard).

When required for use, one volume of I. is to be mixed with two volumes of II. The copper contained in 10 c.c. of this mixture is precipitated completely, as cuprous oxid, by 0.05 gm. of glucose.

"To determine the quantity of sugar, place 10 c.c. of the mixed soln. in a flask of about 250 c.c. capacity, dilute with H_2O to about 30 c.c., and heat to boiling. On the other hand, the urine to be tested is diluted and thoroughly mixed with four volumes of H_2O if it be poor in sugar, or with nine volumes of H_2O if highly saccharine, and a burette filled with the mixture. When the Fehling soln. boils, add a few gtt. NH_4HO and then 5 c.c. of the urine from the burette, boil again, and continue the alternate addition of diluted urine and boiling of the mixture until the blue color is quite faint. Now add the diluted urine in quantities of 1 c.c. at a time, boiling after each addition until the blue color just disappears. Have ready a small filter, and, having filtered through it a few gtt. of the hot mixture, acidulate the filtrate with acetic acid, and add to it 1 gtt. soln. of potassium ferrocyanide. If a brownish tinge be produced, add another ½ c.c. of dil. urine to the flask, boil, and test with ferrocyanide as before. Continue this proceeding until no brown tinge is produced. The burette reading, taken at this point, gives the number of c.c. of dilute urine containing 0.05 gm. glucose, and this divided by 5 or 10, according as the urine was diluted with 4 or 9 volumes of H_2O, gives the number of c.c. of urine containing 0.05 gm. sugar. The number of c.c. urine passed in twenty-four hours divided by 20 times the number of c.c. containing 0.05 gm. glucose, gives the elimination of glucose in twenty-four hours in grams.

Example. Urine in 24 hours = 2,436 c.c.
Fehling's soln. used = 10 c.c.
Urine diluted with 4 vols. H_2O.
Burette reading = 18.5 c.c.

$$\frac{18.5}{5} = 3.7 = \text{c.c. urine containing 0.05 gm. glucose.}$$

$$\frac{2,436}{3.7\times 20} = 32.92 = \text{grams glucose eliminated in 24 hours."}$$

(Witthaus' *Urinalysis.*)

ANATOMY AND PHYSIOLOGY.

9. The venous blood current is maintained by (1) the action of the heart, (2) muscular contraction, and (3) aspiration of the thorax.

The pulmonary arteries carry venous blood.

10. The causes producing the *first* sound of the heart are not definitely ascertained; the following are supposed to be causatory factors: (1) The vibration and closure of the auriculo-ventricular valves, (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall.

The *second* sound is caused by the vibration due to the closure of the semilunar valves.

11. The *amount* of bile secreted in twenty-four hours varies from about 500 c.c. to 900 c.c.

The *composition* of the bile may be shown in the following table, which presents the averages of three analyses given by Hammarsten, the results are given in parts per thousand.

Water	971.380
Solids	28.620
Mucin and pigments	4.910
Bile salts	12.107
Taurocholate	2.431
Glycocholate	9.766
Fatty acids from soaps	1.200
Cholesterin	1.243
Lecithin and fats	0.970
Soluble salts	7.360
Insoluble salts	0.317

The *functions* of the bile are: (1) to assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach, and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.

13. The glands of the small intestine are: (1) Glands of Lieberkuhn, (2) glands of Brunner, (3) Peyer's patches.

The function of these glands is to contribute towards the composition of the succus entericus.

14. *"Mechanism of Accommodation.*—The lens is an elastic structure, and when released from the flattening influence of its suspensory ligament tends to assume a spherical shape. During accommodation the ciliary muscle (especially the circular fibers) contracts, drawing forward the chorioid and relaxing the suspensory ligament; this diminishes the tension of the lens capsule and allows the inherent elasticity of the lens to increase its convexity. The change in curvature affects chiefly the anterior surface of the lens. This is Helmholtz's theory and the one usually accepted. Lately Tscherning has advanced a different theory; he maintains that the ciliary muscle increases the tension of the suspensory ligament during contraction and that this causes peripheral flattening of the lens with bulging anteriorly at its center. The act of accommodation is accompanied by contraction of the pupil, and (in binocular vision) by convergence of the visual lines." (May's *Diseases of the Eye.*)

HISTOLOGY, PATHOLOGY, AND BACTERIOLOGY.

2. The layers of mucous membrane are: (1) Epithelium, (2) basement membrane, (3) fibrous and elastic connective tissue, (4) sometimes involuntary muscular tissue.

Mucous membranes are found lining all passages which connect the interior of the body with the surface. The principal ones are the gastrointestinal tract, the pulmonary tract, and the genitourinary tract.

5. Peptic ulcer of the stomach is usually situated on the posterior wall and lesser curvature, near the pyloric orifice; it is generally small and round or oval; clean punched out, and with sloping edges, giving a funnel shaped appearance with the apex outward; the edges and floor are generally pale and smooth. These ulcers may be single or multiple, and are liable to terminate in hemorrhage and perforation.

6. In *pernicious anemia* the blood would show: (1) A diminution in the number of red corpuscles; (2) a relative increase in the amount of hemoglobin; (3) poikilocytosis; (4) the presence of nucleated red cells; (5) variation in the size of the red cells; (6) the leucocytes *may be* diminished.

7. *Carcinoma* is apt to occur at a later age; is found in structures derived from the epiblast or hypoblast; possesses a fibrous stroma, in which are found both blood-vessels and lymphatics; metastasis is by the lymphatics.

Sarcoma is apt to occur earlier; is found in structures derived from the mesoblast; there is no stroma between the cells; the blood-vessels are in direct contact with the tumor cells; there are no lymphatics; metastasis is by the blood-vessels.

8. The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbolfuchsin, and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods, while all other bacteria will appear blue.

10. The Widal serum reaction "depends upon the fact that serum from the blood of one ill with typhoid fever, mixed with a recent culture, will cause the typhoid bacilli to lose their motility and gather in groups, the whole called "clumping." Three drops of blood are taken from the well-washed aseptic finger tip or lobe of the ear, and each lies by itself on a sterile slide, passed through a flame and cooled just before use; this slide may be wrapped in cotton and transported for examination at the laboratory. Here one drop is mixed with a large drop of sterile water, to redissolve it. A drop from the summit of this is then mixed with six drops of fresh broth culture of the bacillus

(not over twenty-four hours old) on a sterile slide. From this a small drop of mingled culture and blood is placed in the middle of a sterile cover-glass, and this is inverted over a sterile hollow-ground slide and examined. A positive reaction is obtained when all the bacilli present gather in one or two masses or clumps, and cease their rapid movement inside of twenty minutes." (From Thayer's *Pathology.*)

NERVOUS DISEASES AND DISEASES OF THE EYE AND EAR.

6. *Hordeolum* is an abscess or inflammation in the tissues about the follicle of an eyelash.

Chalazion is a tumor in the eyelids due to obstruction of the duct in a Meibornian gland.

Ectropion is an eversion of the eyelid with exposure of conjunctival surface.

Entropion is an inversion of the margin of the eyelid and eyelashes.

Ptosis is a drooping of the upper eyelid, generally due to paralysis.

Astigmatism is a condition in which owing to a greater curvature of the eye in one meridian than in others, the refractive power of the eye varies.

Myopia is a condition in which the antero-posterior axis of the eye is abnormally long, and parallel rays are focused in front of the retina.

10. (1) Catarrhal conditions of the nose and throat, (2) infection from the external ear, Eustachian tube, or elsewhere, (3) traumatism.

MATERIA MEDICA AND THERAUPETICS.

1. *Narcotics* are agents that produce sleep or stupor and allay pain. Example—opium.

Ancsthetics are agents which destroy sensation for a period of time. Example—chloroform.

Sedatives are agents which allay excitement and functional activity, and sometimes tend to diminish pain. Example—potassium bromide.

2. *Diuretics* are agents which promote the secretion of urine. Examples—water, alcohol, potassium acetate.

Diaphoretics are agents which promote the secretion of sweat and increase the activity of the skin. Examples—alcohol, Dover's powder, Turkish bath.

6. *Three heart stimulants:* (1) Alcohol, dose ʒj to ʒij of spiritus frumenti diluted; (2) ammonia, dose of aqua ammonia ɱxv to xx, well diluted; (3) sparteine sulphate, dose gr. 1/16 to ¼.

7. For *acute bronchitis:*

℞ Vini ipecacuanhæ.....ʒij
Liquoris potassii citratis.....ʒiv
Tincturæ opii camphoratæ
Syrupi acaciæ.....aa ʒj Misce.

Sig:—One tablespoonful three times a day.

For *chronic constipation:*

℞ Aloin.....gr. vj
Atropinæ sulphatis.....gr. ¼
Strychninæ sulphatis.....gr. j. Misce.

Fiat massa in pilulas no. xxx dividenda.

Sig:—One pill two or three times a day.

For *acute cystitis:*

℞ Potassii acetatis
Potassii citratis.....aa ʒij
Aqua destillatæ.....q.s. and ʒvj Misce.

Sig:—One tablespoonful three times a day.

9. *Four hypnotics:*—(1) chloral hydrate; dose, gr. xv to xx. (2) Sulphonal; dose, gr. xv to xxv. (3) Trional; dose, gr. xv to xxv. (4) Paraldehyde; dose, ɱxxx to ʒi.

Four emetics:—(1) Apomorphine hydrochloride; dose, gr. 1/10 hypodermically. (2) Copper sulphate; dose, gr. iv to vj in water. (3) Zinc sulphate; dose, gr. x to xv in water. (4) Turpeth mineral; dose, gr. iij to v.

10. *Alkaloids* are active nitrogenous principles, alkaline in reaction, and capable of uniting with acids to form salts in the same way that ammonia does. Example—strychnine.

"*Serum therapy* proper is the prophylactic and curative treatment of certain infectious diseases by the subcutaneous or intravenous administration of a blood-serum containing an antibody which is specific to the particular disease." (Potter's *Materia Medica.*)

Examples:—(1) Diphtheria antitoxin; dose, 3,000 units; immunizing dose, 500 units; indicated in diphtheria. (2) Antitetanic serum; dose ʒijss to v; indicated in tetanus. (3) Antivenomous serum; dose, ʒijss to viij; indicated in snake bite.

REQUIREMENTS FOR MEDICAL LICENSURE.

In the following table the States requiring of the candidate both a diploma from a recognized college and an examination are printed in roman; those requiring either a diploma or an examination, in italics; those requiring an examination only, in small capitals.

State	Fee	State	Fee
Alabama	$10.00	Nebraska	$25.00
Arizona	10.00	*Nevada*	25.00
Arkansas	10.00	New Hampshire	10.00
California	20.00	New Jersey	25.00
Colorado	25.00	*New Mexico*	25.00
Connecticut	15.00	New York	25.00
Delaware	10.00	North Carolina	10.00
District of Columbia	10.00	North Dakota	20.00
Florida	15.00	Ohio	25.00
Georgia	10.00	Oklahoma	5.00
Idaho	25.00	Oregon	10.00
Illinois	25.00	Pennsylvania	25.00
Indiana	10.00	Rhode Island	10.00
Iowa	25.00	South Carolina	10.00
Kansas	15.00	South Dakota	20.00
Kentucky	10.00	Tennessee	10.00
Louisiana	10.00	Texas	10.00
Maine	10.00	Utah	15.00
Maryland	15.00	Vermont	15.00
Massachusetts	20.00	Virginia	10.00
Michigan	25.00	Washington	25.00
Minnesota	10.00	West Virginia	10.00
Mississippi	10.00	Wisconsin	10.00
Missouri	15.00	Wyoming	25.00
Montana	15.00		

BULLETIN OF APPROACHING EXAMINATIONS.†

State.	Name and address of secretary.	Place and date of next examination.	
Alabama*	W. H. Sanders, Montgomery	Montgomery	August 1–6
Arizona*	Ancil Martin, Phoenix	Phoenix	Oct. 7
Arkansas*	F. T. Murphy, Brinkley	Little Rock	July 9
California	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	August 6
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	October 1
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	July 9
Delaware	J. H. Marion, Dover	Dover	Dec. 10
Dis. of Col. bia	W. C. Woodward, Washington	Washington	July 11
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	Nov. 20
Georgia	E. R. Anthony, Griffin	Atlanta	October 8
Idaho	J. L. Conant, Jr., Genesee	Boise	October 1
Illinois	J. A. Egan, Springfield	Chicago	July 25
Indiana	W. T. Gott, 120 State House, Indianapolis	Indianapolis	October 22
Iowa	Louis A. Thomas, Des Moines	Des Moines	Sept. —
Kansas	T. E. Raines, Concordia	Topeka	October 8
Kentucky*	J. N. McCormack, Bowling Green	Louisville	October 2
Louisiana	F. A. La Rue, 211 Camp Street, New Orleans	New Orleans	October 15
Maine	Wm. J. Maybury, Saco	Augusta	July 9
Maryland	J. McP. Scott, Hagerstown	Baltimore	Dec. 3
Massachusetts*	E. B. Harvey, State House, Boston	Boston	July 9
Michigan	B. D. Harrison, 205 Witney Building, Detroit	Lansing	October 8
Minnesota	W. S. Fullerton, St. Paul	St. Paul	October 1
Mississippi	J. F. Hunter, Jackson	Jackson	October 8
Missouri	J. A. B. Adcock, Warrensb'g.	Mexico	July 9
Montana*	Wm. C. Riddell, Helena	Helena	October 1
Nebraska	Geo. H. Brash, Beatrice	Lincoln	
Nevada	S. L. Lee, Carson City	Carson City	August 5
N. Hampshire*	Henry C. Morrison, State Library, Concord	Concord	July 9
New Jersey	J. W. Bennett, Long Branch	Trenton	October 22
New Mexico	B. D. Black, Las Vegas	Santa Fe	December 2
New York	C. F. Wheelock, Unv. of State of New York, Albany	New York, Albany, Syracuse, Buffalo	June 25
N. Carolina*	G. T. Sikes, Grissom	Winston, Salem	May, 1908
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks	July 2
Ohio	Geo. H. Matson, Columbus	Columbus	Dec. 10
Oklahoma*	J. W. Baker, Enid	Guthrie	Sept. 24
Oregon	B. E. Miller, Portland	Portland	
Pennsylvania	N. C. Schaeffer, Harrisburg	Philadelphia, Pittsburg	Dec. —
Rhode Island	G. T. Swarts, Providence	Providence	October 3
S. Carolina	W. M. Lester, Columbia	Columbia	June 9, '08
S. Dakota	H. E. McNutt, Aberdeen	Sioux Falls	July 10
Tennessee*	T. J. Happel, Trenton	Memphis, Nasbville, Knoxville	May, 1908

*No Reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Delaware.—Although more than twenty persons had made application for examination at the June session of the Delaware Examining Board, only four presented themselves at the time of examination. Of these three were recommended to the Medical Council for license to practice medicine and surgery in the State. The reason for the failure of so many applicants to present themselves for examination was probably that they had overlooked the change recently made by the Legislature in the preliminary requirements. The applicant who failed had a general average of 62.7 per cent. Those who passed had averages of 81.2, 81.5, and 90.7 per cent.

New Instruments.

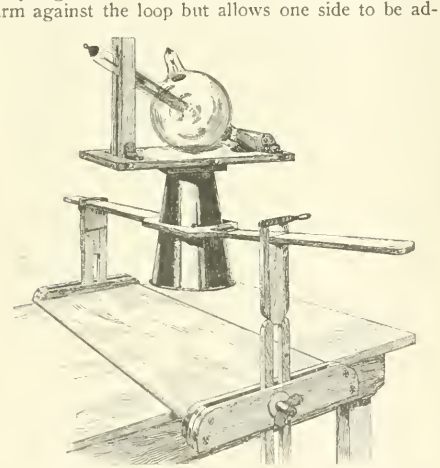
A NEW *X*-RAY COMPRESSION DIAPHRAGM.

By W. I. LE FEVRE, M.D.,

CLEVELAND, O.

THE accompanying pictures illustrate an *x*-ray compression diaphragm that I have designed. It is easily and quickly adjusted to any position and when not in use can be folded into a small space, about the size of a suit case. The apparatus consists of a base board 12 inches wide, 26 inches long, by ½ inch thick. This is grooved on the bottom so that an iron

bolt can pass through from one end to the other, with a thumb nut on one end. When this thumb nut is tightened it locks both upright pieces in any position they are placed. The end upright pieces are slotted so they can be placed at any height or tilted to any angle. The one on the far side has a steel loop that holds the shaft of the paddle with a spring cushion beneath which keeps the paddle firm against the loop but allows one side to be ad-



justed higher than the other if necessary. The other upright has an eccentric lever for locking the handle of the paddle when it is brought down into position. The tube holder is upholstered with leather and lined with sheet lead, so as to cut off all diffused light. The spring bars automatically hold the tube so that the plane of the anode is parallel with the plate. The metal funnel has a rubber cushion around the bottom so that it is more comfortable for the patient and prevents shock if the current should leak to the tube holder. In taking radiographs where it is not desirable to use the funnel, the tube holder and diaphragm can be locked to the paddle and then adjusted to any position. In taking stereoscopic pictures, the uprights can be adjusted to the desired angle on one side of the perpendicular and then to the same angle on the other, without moving the tube or diaphragm on the paddle. This compressor will fit upon any table, can be quickly adjusted, and one thumb nut locks it securely.

INTRACRANIAL TUMOR AND ITS TREATMENT.*

By WILLIAM M. LESZYNSKY, M.D.,

NEW YORK.

ATTENDING NEUROLOGIST TO THE LEBANON HOSPITAL; CONSULTING NEUROLOGIST TO THE HARLEM HOSPITAL, ETC.

The subject of intracranial or cerebral tumor has been of increasing interest to neurologists and surgeons during the last fifteen years. Within this period our knowledge of cerebral localization has been materially augmented through clinical observation and the accumulated autopsy records in many cases.

The designation intracranial tumor includes all new growths within the cranial cavity, originating either in the brain substance or its envelopes, or from the bone or periosteum. Cysts must also be included, for their presence produces symptoms indistinguishable from solid tumors. The same may be said of aneurysm of the Sylvian, basilar, or internal carotid artery, which, although very rare, may occur at any age.

The symptoms of intracranial tumor are classified as "general" and "focal" or "localizing." The principal general symptoms are headache, vomiting, vertigo, hebetude or stupor, general convulsions, and optic neuritis or choked disks. Among the focal or localizing symptoms are local spasms or paralysis affecting the face or extremities, hemianopsia, ocular palsies, the various forms of aphasia, and the involvement of the special senses. Such signs must be assiduously sought and, when discovered, subjected to careful analysis and interpretation.

The general symptoms occur regardless of the location or character of the growth. It may be mentioned here that there are three regions of the brain in which a neoplasm would not give rise to focal symptoms. These are the orbital surface of the prefrontal lobe, the right temporal lobe, and the lateral lobe of the cerebellum. As in other organic affections of the nervous system, the symptoms are unmistakable when the disease is well advanced. If any prospect of amelioration or cure is to be entertained in cases of brain tumor, the diagnosis must be made as early as possible.

It behooves the general practitioner to give more careful attention and study to patients complaining of intense and persistent headache, and to consider the possibility of cerebral neoplasm in every case, for headache and vomiting (unrelated to the ingestion of food) are among the initial symptoms of brain tumor. In an article on Headache, in Wood's "Reference Handbook of the Medical Sciences," I have thus described this type of headache: "It is one of the most constant and obtrusive symptoms. In exceptional instances, headache may be absent during the entire course of the disease. But such a condition is very rare, the headache varying in intensity in different cases. Occasionally it may be of a mild character. As a rule, it attains great severity, preventing sleep, and at times becoming so unendurable that the patient has been known to commit suicide. Sometimes the pain is paroxysmal, but more frequently it is almost continuous, with periods of great exacerbation. The headache is usually diffuse, but it may be limited to the forehead, parietal region, or occiput, changing its location from time to time. The seat of the pain in the cranium does not necessarily imply that the growth is subjacent. When the pain is confined to the frontal region it by no means indicates that the frontal lobes are involved, for such pain often occurs in cerebellar tumor. The presence of persistent occipital pain extending to the neck would lead us to assume that the growth is probably situated in the posterior cranial fossa. If the headache is limited to a circumscribed area it most frequently corresponds with the location of the growth which has also involved the underlying meninges. If it be confined to one side of the head, the probability is that the tumor is on the same side. This is not an invariable rule, however. The pain is aggravated by everything that interferes with the cerebral circulation. It is thus made worse by psychical excitement, alcohol, coffee, muscular activity, coughing, straining at stool, sneezing, etc. It is universally assumed that the headache is produced by irritation of the numerous branches of the trigeminus supplying the dura. The dura may also be stretched and irritated as a result of intracranial pressure. If this be true, in the former condition the pain would probably be circumscribed, while in the latter we would expect it to be diffused. Clinical facts, however, cannot always be reconciled with this view."

Transient attacks of blindness or failing vision often lead these patients to consult an ophthalmologist. Choked disks are then discovered and it is through this indirect channel that many cases have come under my observation. Every patient, young or old, who complains of continuous or paroxysmal headache, with or without vertigo or vomiting, should be subjected to an ophthalmoscopic examination as a routine measure. The importance of this procedure is evident. Although optic neuritis does not appear in every case of brain tumor in its early stage, it does occur sooner or later in from 80 to 90 per cent. In rare instances it may be absent throughout the entire course of the disease. It must always be borne in mind, however, that a high degree of optic neuritis is not incompatible with the preservation of normal vision. The danger of optic neuritis is its termination in optic atrophy and complete blindness. Headache is the most frequent, and optic neuritis the most important general symptom of brain tumor.

With a knowledge of the symptomatology and course of the disease, the diagnosis, as a rule, is

*Read before the Harlem Medical Association, March, 1907.

not difficult. It must be admitted, however, that in some instances the diagnosis becomes one of the most perplexing problems in medicine, when we realize that an intracranial growth may be present without pronounced manifestations.

The neurologist very frequently sees these patients, whose disease has remained unrecognized, after various symptomatic remedies have been unsuccessfully employed, and it is quite a commonplace occurrence for them to have undergone prolonged treatment for gastric disorders or "biliousness" before the true nature of the malady is suspected. I recently examined a woman in whom the diagnosis rested between a slowly progressing brain tumor and chronic basal meningitis. She was then delirious, with a pulse of 80 and temperature of 103°, unequal pupils, ocular paralysis, and double optic neuritis. She died a few days later. On account of attacks of persistent vomiting, exploratory laparotomy had been performed several months before for supposed cancer of the stomach. In other cases of cerebellar tumor, gastric lavage had been practised, as the vomiting and vertigo were attributed to disturbance of digestion.

In some instances, headache, vomiting, and optic neuritis terminating in atrophy, may exist for many months before localizing signs begin to appear. Yet it is not always safe to base the diagnosis of brain tumor upon the general symptoms, for the same may be present in cases of chronic basal meningitis without any apparent implication of other cranial nerves. In doubtful cases the diagnosis must be made by exclusion. The presence of optic neuritis is indicative of an intracranial lesion, and at once eliminates the functional type of headache associated with migraine, hysteria, neurasthenia, and hypochondriasis. Indeed, attacks of unilateral headache accompanied by vomiting and simulating migraine may antedate other manifestations. Epileptic convulsions occurring for the first time late in life (in the absence of chronic nephritis) should always lead to examination for evidence of cerebral tumor, for epileptic attacks may precede all other obtrusive symptoms for several years. More attention and consideration should be given to convulsive seizures limited to one side of the face or one extremity without loss of consciousness. Such attacks are too often ascribed to hysteria, but in the majority of instances are either of uremic origin or the result of cerebral disease, possibly tumor.

Furthermore, the symptoms of brain tumor may be simulated by acquired internal hydrocephalus, brain abscess, basal meningitis, cerebral arteriosclerosis, chronic nephritis, cerebral syphilis, encephalitis, and lead encephalopathy.

As the limits of this paper will not permit of a detailed discussion of the differential diagnosis, I will briefly mention only a few important criteria. In the first place, let me call your attention to the necessity of invariably excluding chronic Bright's disease (usually the cirrhotic form) before making the diagnosis of brain tumor. In the former affection uremic symptoms may be present, such as headache, vomiting, vertigo, somnolence, or insomnia, optic neuritis, unilateral convulsions without loss of consciousness, monoplegia, or hemiplegia. An erroneous conclusion may be prevented by a careful analysis of the urine, and the condition of the heart and vascular system. When such symptoms occur in a young person, however, the chances are all in favor of brain tumor.

In *brain abscess* there may be headache, vomiting, hebetude or stupor, vertigo, general convulsions, slow pulse, etc. Optic neuritis frequently occurs, and is often limited to the side on which the abscess is situated. It rarely reaches the degree of choked disk as in tumor cases, and yet the differentiation can usually be made with certainty. Cerebral abscess is either of traumatic origin, *i.e.* from an infected wound of the scalp or cranium, or the infection originates in a focus of suppuration in the middle-ear, or is due to metastasis. By far the largest number of cases of brain abscess are of otitic origin, and affect the temporosphenoidal lobe or the cerebellum. When symptoms of abscess become manifest, the course is usually more rapid than in tumor.

Syphilitic basal meningitis is often attended by severe headache and vomiting, and choked disks with retinal hemorrhages may be present. It is only through the history of the case, the rapid development of the symptoms, and the involvement of the cranial nerves that the diagnosis can be made. The degree and type of optic neuritis is often the same as in cerebral tumor.

It is not expected that the general practitioner without special neurological training should be able to correctly localize a cerebral neoplasm. But, with due care and diligence in observation, he should at least make a provisional diagnosis of organic brain disease.

The experienced neurologist often finds the symptoms of intracranial tumor so perplexing that it may be extremely difficult to decide whether they are due in greater part to complicating internal hydrocephalus, or to the direct effect of the tumor itself. Increase of cerebrospinal fluid is an almost invariable accompaniment of an intracranial growth. A positive differentiation between acquired internal hydrocephalus and cerebral tumor is often impossible. At times it is extremely difficult to reach a definite conclusion as to the location and character of the neoplasm even after the patient has been under hospital observation.

In the case of a boy sixteen years of age (MEDICAL RECORD, April 24, 1889) with severe and persistent headache, vomiting, and choked disks, the diagnosis of brain tumor had been made by several observers. In the course of two years the headache and vomiting subsided, the optic neuritis disappeared, and he made a complete recovery with normal vision. I examined him from time to time during a period of twelve or fourteen years, but there was no recurrence of the symptoms and he continued in perfect health.

Again, cases occasionally occur which simulate the clinical picture of brain tumor involving either the cerebral hemisphere or the cerebellum, which terminate in permanent recovery either spontaneously or under mercurial treatment, leaving atrophy of the optic nerves as the only residual symptom. They have been well described by Nonne (*Deutsche Zeitschrift für Nervenheilkunde*, Bd. 27, p. 169, 1904), and analogous cases have come under my observation.

Mistakes have been made by skilled observers in assuming that the growth was in the posterior fossa, but, at autopsy, being found in the prefrontal region. Such cases are on record, and I have quite recently had a somewhat similar experience. The patient was a girl nineteen years of age who had always been healthy and had never contracted syphilis. She fell downstairs, striking her head in the right occipital region, and was unconscious about five minutes. Severe headache and vomiting soon followed and persisted with acute exacerbations for several months. Later, she had vertigo for three days, and

blindness supervened. Six months after the injury she was admitted to the hospital, where she remained for several months. At the autopsy a glioma was found in the median line in front of the anterior horns of the dilated lateral ventricles. The indications and symptoms which led to the diagnosis of a tumor probably located in the posterior fossa, with pressure upon or involvement of the upper cervical nerves, were the following: occipital trauma; frequent attacks of occipital headache, with rigidity of the neck and retraction of the head; persistent horizontal nystagmus; paresis of both externi; frequent occurrence of spontaneous pain and tenderness on pressure over both suboccipital regions, associated with darting pains and paresthesiæ in both upper extremities; and the absence of permanent involvement of the pyramidal tract or other cranial nerves. The lack of disturbance of equilibration led to the assumption that if the tumor involved a lateral lobe of the cerebellum it did not make pressure upon the vermis. Many of the other symptoms and their fluctuating character were ascribed to associated internal hydrocephalus and indirect pressure.

In an article on "The False Localizing Signs of Intracranial Tumor" (*Brain*, 1904, p. 491), Collier has shown that in many cases of long duration the posterior and inferior parts of the cerebellum have become pushed down and backwards into the foramen magnum, with the medulla forming a cone-shaped plug, tightly filling up the foramen magnum. This explains why indirect pressure resulting from a prefrontal tumor may simulate symptoms of a subtentorial growth.

What can be done for the relief or cure of these patients, whose disease generally terminates fatally after a few years' duration?

When syphilis is suspected or known to exist, the administration of mercury and iodides may prove of value, although they are often not of much use even when a syphilitic gumma is present. It is also to be remembered that other forms of cerebral tumor, especially sarcoma, are benefited by antisyphilitic treatment, and that at times remissions occur spontaneously. For alleviating the headache, some of the coal tar products are available. If their employment is not satisfactory, then ergot or morphine may be administered subcutaneously. At times, free catharsis proves of temporary service in relieving the intracranial pressure. Lumbar puncture and the withdrawal of cerebrospinal fluid often increases the headache. It is usually of no benefit and may endanger life if a large quantity of fluid is withdrawn. These methods often prove the banefulness and unwisdom of procrastination. In many instances our only hope lies in surgical intervention.

Operation should therefore be resorted to as soon as a positive diagnosis is made, and after the condition has proved unamenable to medical treatment. If the tumor has been accurately localized and is accessible, its removal should be undertaken if practicable. *X*-ray examination cannot be relied upon as a means for correct localization of an intracranial neoplasm. In exceptional cases, however, it has proved valuable.

There are at present a small but increasing number of surgeons who are specially qualified to do this kind of surgical work. Special training is essential before such operations are undertaken, and it would add greatly to the advantage of the surgeon and the patient for the former to possess a practical knowledge of brain anatomy and cerebral localization. It has often been asserted that one of the contributing causes of failure in these operations is erroneous neurological diagnosis. This criticism is to a certain extent true, but, when we consider the perplexities often attending the diagnosis of brain tumor, it is not at all surprising that mistakes sometimes occur to the most experienced observers. In obscure or doubtful intraabdominal disease in which exploratory laparotomy is a comparatively harmless procedure, more inexcusable diagnostic errors have been revealed. The relief of intracranial pressure and the prevention of blindness is of paramount importance, and makes it imperative that the so-called decompressive or palliative operation be performed without delay. Increased intracranial pressure is responsible in greater part for the general symptoms and is one of the principal causes of the optic neuritis. It is usually productive of more suffering than the direct pressure of the tumor itself. Under such circumstances, the question whether the tumor can be safely removed or not is a secondary matter. This operation is done by making a large osteoplastic flap, or a large opening in the skull with complete removal of the bone, and opening the dura, and in the hands of an experienced operator is almost without danger. Krause (*Neurologisches Centralblatt*, No. 20, 1906, p. 968) says that such a surgical measure may be undertaken with as much justification as a gastrotomy for cancer of the esophagus. When the operation is performed for the permanent relief of intracranial pressure, and the tumor is either inaccessible or not localized, the point of selection is usually over the right temporal region. For, in this location no harm can result through the formation of a cerebral hernia, as this is a so-called "silent" area, unless it be in a left-handed person. In right-handed people, the region of the first and second temporal convolutions on the left side contains the cortical center for hearing and the auditory memories of spoken language.

Let me impress upon you the very important and well-established fact that, in the majority of cases, if operation is delayed until the vision becomes seriously impaired, optic atrophy and blindness will be the inevitable result. Leslie Paton (Transactions of the Ophthalmological Society of the United Kingdom) has carefully reported thirty cases of brain tumor in which useful vision was saved in twenty-two as a result of operation. In several of my cases herein reported blindness was present when the patient first came under observation. In another case, operation was deferred for several months. In the meantime, vision became hopelessly affected. The operation was successful in exposing and draining a subcortical cyst, but the patient became totally blind although she recovered from the hemiplegia and other symptoms.

In doubtful cases, particularly when a cerebellar growth is suspected and when vision is not at all impaired, we should not be too hasty in recommending surgical intervention. Besides, we must always bear in mind that it is often quite difficult and at times impossible to differentiate between acquired internal hydrocephalus and cerebellar tumor.

We must admit that, notwithstanding the remarkable advances in neurology and surgical technique, the greater number of brain tumors are inaccessible to operation, and, although occasional brilliant results are achieved, the surgical treatment of brain tumors is still a difficult problem. Moreover, quite a large number of brain tumors cannot be localized. The successful removal of tumors from the frontal, temporal, parietal, and occipital regions, as well as from the cerebellum, the cerebello-pontile angle, and the ablation of the Gasserian ganglion, has invali-

dated the former dictum of Von Bergmann that "brain surgery is the surgery of the central convolutions."

From a statistical study of 424 cases with autopsy records collected from various sources, Walton and Paul (*Journal of Mental and Nervous Diseases,* August, 1905) have shown that "out of 424 cases 30, or 7 per cent., were operable; 338, or 80 per cent. were inoperable, and 56, or 13 per cent., were placed in the doubtful class. The combination of operable and possibly operable therefore reached 20 per cent." By a process of further elimination, the number of operable cases was reduced to approximately 3.3 per cent. Nevertheless, the brilliant work of many of our confrères both at home and abroad within the last decade has greatly increased our confidence in surgical operation in suitable cases. Successful achievements in the extirpation of brain tumors has added additional laurels to American surgery.

Spiller and Frazier (*Journal of the American Medical Association,* Sept. 1, 1906) have reviewed the literature and reported the histories of fourteen cases of brain tumor that have been relieved by the palliative operation for "cerebral compression," and have reached the following conclusions: "Palliative operations should be performed early in every case in which symptoms of brain tumor are pronounced, and before optic neuritis has advanced far, especially when syphilis is improbable or antisyphilitic treatment has been employed." This is a sound doctrine, and represents the consensus of opinion of all experienced neurologists.

In a recent elaborate report of fourteen cases of brain tumor submitted to operation within the last three years, Oppenheim (Beitrag z. Diag. u. Therap. d. Geschwulste des Centr. Nerv. Syst., Berlin, 1907) has shown what brilliant results may sometimes be achieved by a careful selection of cases, accuracy in diagnosis, and operation by an experienced surgeon.

For the purpose of illustration I have selected for this paper a brief report of several cases of intracranial tumor that have been under my observation, and I would ask your close attention as they possess some exceedingly interesting features in exemplification of the foregoing remarks.

Case I.*—A merchant, 56 years of age, of Utica, N. Y., a patient of Dr. James H. Glass, was examined in May, 1899 (eight years ago). Clonic spasm in the muscles of the left leg occurring at brief intervals, and followed by transient weakness in the limb, began two years before. This was soon followed by similar attacks involving the left hand and forearm. After these attacks ceased, left hemiparesis gradually developed. He never suffered from headache, vomiting, or vertigo. No history of syphilis, head injury, or alcoholism. Examination revealed double optic neuritis with preservation of normal central vision and slightly contracted fields; left hemiparesis without involvement of the face, and exaggeration of the left knee-jerk.

Diagnosis, intracranial tumor of slow growth involving the arm and leg centers in the right cerebral cortex. He was then operated upon by Dr. Glass, and an endothelioma three-quarters of an inch in diameter successfully removed from the region indicated. Several months later, the patient began attending to business, and for the past seven years has been following his daily occupation, the present condition of partial hemiplegia being the result of the destruction of brain tissue prior to removal of the growth. A noteworthy feature in this case was the absence of headache and vomiting during the entire course of the disease. Had the diagnosis been made about two years earlier, when the symptoms clearly indicated involvement of the cortical leg center, and the tumor removed at that time, the patient would have been saved from the incapacity associated with a permanent hemiplegia.

Case II.*—C. P., 19 years of age, stenographer, was admitted to the hospital January, 1903. For nine months there had been frontal and occipital headache with vomiting and frequent attacks of vertigo. She had been totally blind for two months as the result of an intense bilateral optic neuritis. There was no history of traumatism or luetic infection. Slight left hemiparesis, including the lower facial distribution, and astereognosis affecting the left hand without disturbance of general sensibility were present. The left knee-jerk was more pronounced than the right.

Four months later her condition had become much worse. There occurred frequent attacks of unconsciousness, and also attacks of tonic and clonic spasm of the left face, arm, and leg, lasting several minutes without loss of consciousness, and followed by transient left hemiplegia and rotary nystagmus. There were fullness of the veins over the forehead indicating venous stasis, and horizontal nystagmus with paralysis of the left externus; condition of blindness and eyegrounds unchanged; the left knee-jerk was exaggerated and accompanied by ankle-clonus and Babinski plantar reflex, but the muscular power was intact in all extremities. Diagnosis, tumor in right hemisphere.

She was operated upon by Dr. McCosh, a large osteoplastic flap being made over the right Rolandic area and the dura opened. There were no indications of tumor formation. The ventricle was punctured and several ounces of cerebrospinal fluid withdrawn. The shock of the operation was comparatively slight. The drainage of the cerebrospinal fluid was very free. It was estimated that up to the time of her death about two pints escaped daily. The intracranial pressure was nevertheless so great as to force the bone flap upward, where it remained, thus causing a permanent projection of the scalp in the form of a cone with an elevation of several inches. The operation resulted in complete cessation of the headache, vomiting, and convulsive attacks. The other symptoms remained unchanged. She died four weeks later of lobar pneumonia, seventeen months after the onset of the symptoms of brain disease. At the autopsy a sarcoma about the size of a hen's egg was found in the right lateral ventricle. At the first examination there was no doubt as to the existence of a brain tumor involving the right hemisphere. The subsequent development of facial spasm, which was for a long time limited to the left side, later the left arm becoming similarly involved, and ultimately the left leg, the attacks of unilateral convulsion without loss of consciousness being followed by transient hemiplegia, presented a characteristic picture of irritative disease affecting the right Rolandic area, originating in the facial center. On account of the predominantly tonic character of the spasm the lesion was thought to be subcortical. In this connection it is worthy of note that local convulsive seizures, when they occur for the first time long after the general symptoms of intracranial tumor, should be disregarded as localizing signs, for they are generally the result of secondary hydrocephalus.

Case III.†—M. W., 28 years of age, single, pho-

tographer, admitted to the hospital October 28, 1903, with the following history: For the last nine months he has had frequent attacks of severe general headache with vomiting. Vision began to fail two months ago, and blindness soon supervened. He now complains of headache, vertigo, and general weakness, with sensation of falling toward the right side. No history of syphilis, alcoholism, or trauma. He was obliged to remain abed, being unable to stand or walk without assistance. The pupils were dilated and rigid, and there was optic neuritis of six diopters with numerous retinal hemorrhages, and slight left hemiparesis including the face. He was delirious at times. He gradually became worse, all of the symptoms mentioned increasing in degree, with the addition of paralysis of the right external rectus, and left astereognosis with ataxia. Diagnosis, tumor involving the right hemisphere. Operation was refused. He was kept in bed, and received iodide of potassium in increasing doses. Two months later all of the symptoms had completely disappeared, the retinal hemorrhages had become absorbed, and his general health was much improved. The house staff and others were inclined to question the correctness of the diagnosis. He was discharged from the hospital at the end of several months, and, excepting the blindness, he was apparently in perfect health.

In the course of a few months the headache, vomiting, and vertigo gradually returned, and toward the end of a year he had frequent paroxysms of delirium, with general convulsions and coma, and died May 25, 1905, two and a half years after the symptoms began. At the autopsy a tumor (sarcoma) the size of a hen's egg was found attached to the internal surface of the right lateral ventricle.

This is the second case of brain tumor occupying the lateral ventricle that has come under my observation. Such cases are extremely rare. Both presented the following analogous features: The patients were intelligent young adults; both had frequent attacks of intense headache, vomiting, delirium, and convulsions; a high degree of optic neuritis, accompanied by total and permanent blindness; astereognosis, without any disturbance of general sensibility; absence of paralysis involving the extremities, but only a slight transient hemiparesis. The diagnosis of brain tumor involving the right hemisphere was made, but the exact location of the neoplasm could not be determined *intra vitam*. In both a sarcoma was found in the right lateral ventricle.

Had a palliative operation been performed in these patients in the early period of the disease, life would have been prolonged and made more endurable and blindness prevented.

Case IV.—Ethel A., school girl, 12 years of age, was brought to me by Dr. Francis Todd of Paterson, N. J., April 24, 1905, with the statement that she was born normally at full term, and has been in good health up to the time of present illness. No history of cranial injury. Seven months ago she often stumbled while walking and had occasional jerking of the left hand. Soon after she complained of general headache, and noticed twitchng of the left facial muscles and of the fingers of the left hand. These attacks occurred twice or thrice daily, usually lasting a few moments, and were followed by complete paralysis of the hand for about five minutes. Later, the left arm became weak, and then the left leg, and the twitching attacks ceased. One month later the headache became more intense and was accompanied by vomiting, vertigo, and mental confusion. She is in constant fear of falling.

Examination showed a bright little girl with a hemiplegic gait. Pupils equal, reaction normal. Vision, right = 20/40 + left = 20/40 —; bilateral optic neuritis with numerous retinal hemorrhages; left facial paralysis, lower branches; complete flaccid paralysis of the entire left upper extremity (the arm dangling like a flail); loss of muscular sense and complete astereognosis with normal general sensibility; flaccid paralysis of the left lower extremity with exaggerated knee-jerk.

The diagnosis was made of a cerebral tumor in the subcortical Rolandic area on the right side and operation advised. Her condition gradually got worse, and three months later she was blind. Operation was then performed by Dr. McCoy of Paterson, and a large subcortical cyst was found as localized. The cyst was evacuated and drained. She has since recovered from the hemiplegia, but is totally blind from optic atrophy.

Had the operation been done when first advised, her vision might have been saved.

Case V.—S. S., 25 years of age, admitted to the hospital January 4, 1906, with the following history: Two years ago he received a fist blow over the right temple. The blow did not seem to affect him very much, and was not followed by any immediate symptoms. During the following six months he complained of severe pain over the left side of the head and face, and paroxysmal attacks of headache and vomiting lasting a few hours. The pain increased, the vision began to fail, and two months ago he became blind. No history of alcoholism or syphilis.

Well-nourished man weighing 160 pounds; pupils equally dilated and rigid; motility of eyeballs normal; vision equals perception of light; bilateral choked disks of five diopters without retinal hemorrhages; slight left facial paresis of lower branches; tenderness on percussion over the right parietal region; muscular power and resistance well preserved in all extremities with all reflexes intact and of normal type; no objective sensory disturbances.

During his brief stay in the hospital he had frequent paroxysms of severe pain in the distribution of the right trigeminus and over the right side of the head, often screaming during the attack. The withdrawal by lumbar puncture of 25 c.c. of cerebrospinal fluid at once intensified the headache.

Diagnosis, intracranial tumor involving the right hemisphere, probably located in the temporal lobe, and an exploratory operation was under consideration. Two weeks after admission he suddenly became comatose and died within two hours from respiratory failure, the heart beating strongly for several minutes after respiration ceased. The autopsy was limited to the cranial contents. No marks of external violence. When the brain was removed, a spiculum of bone was found projecting from the inner table of the skull through the dura, about two inches above and two inches posterior to the right external auditory meatus. A large solid tumor (endothelioma) 8 × 10 ctm. (3¼ × 4 inches) originated at this point, being adherent to the dura and spiculum of bone, lying in the middle fossa and partly in the posterior fossa, compressing the right temporosphenoidal lobe but nonadherent to the brain. One of the interesting features of this case was that direct traumatism was the cause of the growth, although the injury to the head was not considered of much consequence at the time it was inflicted. The time elapsing between the injury and death was two years. The site for operation was to have been in the location preferably selected for cerebral decompression when the position of the

growth is uncertain, *i.e.* over the right temporal region. Had the operation been undertaken as intended, the tumor would have been at once exposed and easily removed.

In conclusion, permit me to state that I have attempted to present only a brief general outline of our present knowledge of the diagnosis and treatment of patients with intracranial tumor.

In suitable cases the palliative operation should be performed as soon as practicable, for it relieves the headache, vertigo, and vomiting, prevents blindness, and prolongs life indefinitely, conditions which, as a rule, cannot be accomplished by any plan of medication.

616 Madison Avenue

THE IMPORTANCE, IN SURGICAL CASES, OF CORRECTING DEFECTIVE UNSTRIPED FIBER, AND SUGGESTION OF METHODS.*

By ALFRED T. LIVINGSTON, M.D.,

JAMESTOWN, N. Y.

The tremendous strides of the last quarter of a century in surgical technique, and in the prevention or control of bacterial infection, are the marvels of this marvelous era of medical practice.

Surgery is both an art and a science. The art appears to-day well-nigh perfected. The science, as related to the infinitesimal germ which so often, even in the recent past, dominated the surgeon, is now almost as perfect. I think I am not unfairly stating the present generally accepted view when I say that these two elements are regarded as the essentials in the practice of this specialty. For many years, however, I have been impressed, both from logical deduction and practical observation, that there is a third essential to the completest attainment of the object sought by the earnest and conscientious surgeon, the greatest possible limitation of mortality.

I recently discovered a reference to this element in a long forgotten manuscript which I wrote more than nineteen years ago. The impressions of that period as to the importance, in surgical cases, of correcting defective unstriped fiber have since been intensified and confirmed by my later observations, and by many recent experiences of more competent observers, who have had larger opportunities for determining the truth or falsity of my theory. My earnest desire to have each member of this society put this theory to the test of practical experimentation is my apology for presenting the subject to you to-night in greater detail than I have previously attempted.

The unstriped muscle fiber is essentially the vital muscle fiber of the body. Its widest distribution is to the walls of the blood-vessels and lymphatics, the remainder, for the most part, constituting the muscular coat of the digestive tract and of the tracts of the secretory organs, the uterus, and the vagina.

Of these systems of unstriped fiber distribution, the circulatory is by far the most important in relation to my subject. The proper circulation of the blood throughout every region of the body is absolutely requisite to the normal activities of each region and the perfect health of the whole organism.

The heart is a quadruple, automatic pump, connected with the beginnings and terminals of the two great vascular circuits, and its perfect working depends upon a perfect state of all the vessels comprising those circuits. These two great circuits have each a threefold purpose, the distribution of nutriment, the collection of waste, and collection and distribution of useful materials absorbed by or secreted from the various special organs through which the blood currents pass.

The science of physiology is by no means perfect. Organs which in my student days were looked upon as useless appendages are to-day recognized as having important functions, and it is not rational to assume that the most profound investigators have even now attained a perfect knowledge of the functions of each individual part of the wondrous and complex mechanism which we term the body. It has, however, become irrational to assume that what we do not now know is of no importance, and the deduction which I make from what we do know is that it is safe to assume that the most equable distribution of the blood to all the parts of the body is a requisite to the highest welfare of each part and of the whole. In the term "equable distribution of the blood" I include those varying proportions of supply which are physiological and belong with special functional action.

As a matter of fact, however, the individual in whom this perfection of equable distribution of blood exists is a *rara avis;* and the explanation of this rarity of perfection is to be found in the fact that somewhere in one or the other or in both of the great vascular circuits there exists an area or areas of defective unstriped fiber; in other words, there are vessels whose muscular fibers are weak and therefore yield more to the general blood pressure than do the vessels whose muscular fibers have better or normal tone, the result of which is, necessarily, that the weak-fibered vessels become surcharged with blood. Corollary to this must be a less than equable supply to some other part or parts, the sequence of it all being that neither the part or parts redundantly supplied, nor the part or parts deficiently supplied, can perfectly perform their respective functions. Moreover, because of the intricate interdependence of the various parts, other parts, which may be normally supplied as to quantity, may suffer because of the altered quality of the blood, due to the regional redundancies and deficiencies. Assume, for illustration, that the relaxed vascular area is in the lungs. This implies a less than normal loading of the oxygen carriers of the venous blood which passes through the defective area, since, where a mesh of vessels is dilated, the embraced mesh of air cells cannot be properly filled with air. If the blood deficiency, corresponding to the pulmonary excess, is in the digestive tract, its important function will be impaired. Then, too, the waste material from the congested area will not be properly carried away and the heart's action will be impeded in proportion to the degree of the circulatory disturbance. We therefore see at once at least four abnormal states resulting from the unstriped fiber relaxation in the lungs. Vascular relaxation elsewhere, as in the kidneys, may be vastly more complex and disastrous in its results.

In considering the relation of defective vascular unstriped fiber to surgical cases, I will begin with one of the most serious, as well as one of the most frequent, conditions which the surgeon encounters, namely, shock. I am well aware that what I shall say to you on this subject does not accord with the accepted views, but, since it is what I most thor-

*Read before the Surgical Section of the New York Academy of Medicine, December, 1904.

oughly believe, I shall doubtless be pardoned the expression of my convictions.

The element which seems to be regarded as the most important in shock, and to which efforts at correction are most strenuously made, is the lowering of blood pressure. The existence of this state I do not pretend to deny, but the making it the prime object of treatment I regard the most serious mistake of surgical practice. The very great lowering of blood pressure in shock is an *effect* of the really essential condition of shock, which is neither the prostration of the heart centers nor that of the so-called vasomotor centers, but is rather the tremendous disturbance of the normal distribution of the blood; the proportion of that fluid which should occupy the peripheral vessels being crowded into the central vessels, particularly those of the abdomen, and this because the unstriped fiber of those central vessels was not able to withstand the sudden increase of pressure due to the closure of the peripheral vessels, and, as overstretched muscular fiber quickly loses its power to contract, the distended vessels continue engorged.

Owing to this extreme inequality of the blood distribution, the peripheral vessels not containing sufficient blood to supply the heart, and the central vessels being unable to contract and send their contents to it, oxygenation being at the same time very deficient, the heart is not supplied with its proper stimulus and therefore contracts but feebly. Because of this and of the small quantity of blood in the arteries, the blood pressure is low. The feeble action of the heart and the low blood pressure suggests the use of the most powerful heart stimulants and the infusing of saline solutions to increase the quantity of fluid in the arteries. I regard such treatment as irrational because it is applied to effects and not to the cause which is the engorged state of the abdominal vessels. The more vigorous action of the heart and the increase of blood pressure which such treatment may effect might even be detrimental, because of their tendency to increase the abdominal engorgement. On the other hand, if the therapeutic effort is directed toward contracting the overdistended vessels of the abdomen, thus sending their excess of blood to the heart and through it to the peripheral vessels, an approximate equalization of the circulation is secured, the heart begins to act easily because well supplied, the blood becomes oxygenated because it circulates through the lungs, and the state of shock has disappeared.

There are three forms of shock with which the surgeon has to deal: the shock of traumatism, the shock of anesthesia, and the shock of operation.

I class anesthesia as a form of shock because, in subjects not previously shocked by traumatism, its effect is essentially that of a traumatism, namely, a great disturbance of the equable distribution of the blood and serious interference with the function of oxygenation. There is always, then, in operation at least a double shock, and, in cases in which operation promptly follows a traumatism, there is a threefold shock, which presents a trying complication for the surgeon and a grave prognosis for the subject. Hence, the surgeon must be profoundly interested in any therapeutic measure that gives assurance or even proximate hope of correcting the state which underlies shock.

There is often a question as to the feasibility of producing sufficient anesthesia to permit operating, the state of the heart, kidneys, or lungs causing apprehension of serious sequel. Analysis of these unfavorable states will show that, for the most part, the basis of the condition is defective unstriped fiber. Many heart symptoms will disappear as soon as an approximate equalization of the circulation is secured. I have observed, and have had reported to me, prompt and striking restoration of the function of the kidneys from a few hypodermics of ergot, which effect must have resulted from correcting a relaxed circulation in those organs. I have many times, also, similarly secured immediate relief from extreme vascular relaxation in the lungs of such extent that the heart distress and sense of suffocation were agonizing.

In view of such experiences as well as of rational theory, I commend the preparation of cases unfavorable for anesthesia by the toning of such unstriped fiber as is deficient in tone, and I believe that the cases are rare which, after such preparation, will not bear necessary anesthesia, if carefully secured.

Retching and vomiting, during or following anesthesia, inconveniences the surgeon in his work, or disturbs the results of his work, and sometimes endangers the life of the patient. Surgeons and anesthetists appear to relate these states to the stomach or its abnormal contents; but, while this may be true in some instances, I am convinced that usually the chief cause is an abnormal relaxation of the vessels of the lower brain, and that previous preparation by toning the relaxed unstriped fiber and the application of such treatment during and following anesthesia will, in most cases, obviate those sequels and, in the extremer cases, will so modify them as to prevent serious results. It is certainly true that in the cases which I have so prepared and treated during anesthesia, some of which have been exceptionally unfavorable, there has been neither retching nor vomiting during the operation, and seldom any vomiting afterward. It seems therefore but a rational conclusion that the toning of the unstriped fiber secured the exceptional results and, if this be true, it must also be true that those disturbances largely depend upon atonic unstriped fiber.

Another of the sequels of operation, which it is desirable, if possible, to avoid, is pain. The word pain at once suggests sensory nerves and the idea of an opiate to dull sensory irritation naturally follows. Although the opiate usually dulls sensory irritation, it also does several other things that are undesirable. First, the general tendency of an opiate is to congest areas of vascular relaxation; secondly, the general tendency of an opiate is to limit or lessen functional activity of secretory glands; thirdly, the opiate tends to lessen peristalsis and therefore to lessen activity of the bowels. There are other objectionable effects of opiates, but these are enough to demonstrate that, in general, if pain can be relieved by means that do not accomplish such effects, it is well to avoid the opiate, and this is especially true of surgical cases, in which each and all of these results may cause much harm.

If pain depended wholly upon a condition of sensory nerve tissue, the opiate might be requisite in spite of its objectionable effects. If pain were "the cry of a nerve for food," then nutritive elements appropriate to such tissue would be the rational indication. The only deduction, however, which I can make from my therapeutic dealing with pain is that, in the mass of instances, it is the sensory interpretation or sign of a vascular plethora about the nerve which gives such signal, and the degree of pain is usually proportionate to the restraint in the tissues themselves, or in their surroundings,

against such vascular plethora. In other words, there is usually involved, in pain, the element of pressure, and that pressure is due to such deficient tone of the unstriped fiber of a vascular area as permits it to become engorged with blood.

It is easy to see the relation of all this to post-operative pain, since shock involves great disturbances of equable blood distribution, and because of the tendency to congestion of tissues which have been injured by traumatism or operation. Practically, I have relieved more pain by correcting defective unstriped fiber than I ever relieved with opiates, and without any of the many undesirable sequels which follow the latter.

The tendency (to which I have just referred) of the vessels, in the region of a traumatism or an operation to undergo relaxation of their muscular coat, and therefore of congestion, forms the basis of one of the greatest obstacles to the success of the surgeon in his work, namely, inflammation.

The surgeon regards the presence of bacteria as the direct cause of inflammation and therefore takes the greatest pains to prevent the infection of wounds, and the application of this principle has certainly marvelously modified mortality. I have long believed, however, that the irritative development of bacteria in relation to local inflammations is chiefly the result of the relaxed state of the blood-vessels of those localities and that if a degree of tone of the unstriped fiber of blood-vessels is secured which will prevent their dilatation to the extent of congestion, such irritative development of bacteria will not occur; also, that, even when such congestion and irritative development of bacteria have occurred to the extent of typical inflammation, a prompt and proper effort to develop tone in those dilated blood-vessels will often abort, or at least distinctly limit the extent of, the inflammation.

Some of my own experiences which I have reported, and recent experiences of many others, demonstrate the correctness of this belief, since typical inflammations have been aborted and extreme inflammations have been modified by means which were not antiseptic in character, but which merely tended to correct abnormal blood distribution and that chiefly, sometimes wholly, by toning relaxed unstriped fiber.

The experiments of Dr. Zwalenburg of California confirm this theory, for when he injected bacteria into the appendix he did not produce appendicitis, but when he mechanically obstructed the circulation in the walls of the appendix, producing congestion of the blood-vessels, he at once developed typical appendicitis from the bacteria ordinarily present. The rational deduction from this is that it is in congested tissues that bacteria irritatively develop, or in which there is developed some irritative element in connection with bacterial multiplication, which determines active inflammation.

It is quite certain that inflammation cannot develop or continue unless there is a congested circulation; also, that congestion implies abnormally relaxed unstriped fiber of vascular walls; also, that such relaxed state of unstriped fiber can be prevented, corrected, or modified, and I therefore hold it to be entirely rational to make use of means that have been demonstrated to be effective for such purpose.

The subject that I have just considered and the one which I shall next consider, namely, repair of tissue, or the process of healing, comprise my earliest thoughts in relating the correcting of deficient unstriped fiber to the field of surgery.

My work at that time, some twenty years ago, was chiefly with disordered states of the brain, and I had become convinced that the most valuable aid which my therapy gave toward restoration to health was in correcting the circulation in that organ by toning the unstriped fiber of those vessels which were relaxed and consequently contained too much blood, and that, when I had accomplished this end, I had given to the activities that determine tissue change and function the best opportunity to perform their important work.

About the time I had reached this conclusion an injury to one of my patients demanded the services of a surgeon, and I employed my friend, the late Dr. Richard J. Levis of Philadelphia. The patient presented the most intense state of suicidal mania that I have ever seen, and the injury, fracture of the skull and extreme concussion of the brain, was accomplished by her suddenly darting from the immediate and close presence of her three special nurses and throwing herself from a height. Her condition was desperate and the doctor's prognosis was grave, indeed he believed she would die. As her death would have been a serious disaster, I considered profoundly what I could do to avert it. It was then that it occurred to me that the same measures which I used in treating an inflammation ought to be preventive of it, and ought also to aid in restoring the shaken-up brain and in healing the fracture and operative wound. I applied those measures vigorously and there was not a moment of the succeeding three weeks in which she was not literally in the hands of two nurses constantly employed in carrying out my orders. At the end of that time she emerged from the unconscious state, not only recovered from the effects of the injury, but entirely recovered also from the insanity, and she has remained well to this day.

Not long after this incident I had another demand, of a different character, for my friend's services, this time for the removal of a diseased mammary gland. I recognized that the subject was quite unfit for the ordeal of operation, being much run down, extremely nervous, despondent, and apprehensive as to the operation and its sequels. I advised a month's delay and at once instituted a preparatory treatment with ergot, with the result that the subject composed herself as calmly for anesthesia and operation as if she were merely lying down for a night's sleep. There was neither retching nor vomiting during the operation nor afterwards; she took nourishment two hours after the operation and at two-hour intervals. She slept three-quarters of an hour after each feeding and the entire succeeding night. There was no postoperative pain, and the extensive wound healed by first intention, and when the stitches were removed the case was concluded.

I am as certain as I can be of anything not mathematically demonstrable that the toning of the unstriped fiber in these cases determined the rapid repair undisturbed by inflammation. The rational character of the theory that the toning of defective fiber assures, and promotes the rapidity of, repair will appear when one considers the elements of the process of healing.

The blood-vessels must bring to the tissues which are to be repaired the nutritive elements which are to be applied, and this can be well accomplished only by vessels through which the blood flows freely, which is not true of congested or engorged vessels. The application of the nutritive elements is more directly made from the perivascular or lymph spaces which are also the channels for carrying away the

waste elements, an equally important and necessary function, and when the blood-vessels are engorged with blood those perivascular spaces are more or less obliterated, which manifestly must interfere with both the application of the new elements and the removal of the waste.

The one deduction from this argument is that the toning of defective unstriped fiber is essential to the best performance of the function of repair.

Before leaving the subject of the circulatory system I will discuss another indication for the toning of its unstriped fiber which the surgeon will frequently recognize. I refer to those states of the heart which cause him to be apprehensive of its utter failure. The surgeon is not credited with an uncontrollable impulse to the use of medication, but I assume that in this matter it is his habit, as well as the general practitioner's, to treat directly and vigorously the failing heart. To this method I do not hesitate to say that I take emphatic exception for these reasons. The greatest obstacle to easy and free action of the heart is unequal distribution of the blood. Such inequality of distribution deprives the heart of a portion of the blood which should be passing through it, equal to the excess which is occupying the overdistended vessels. Such inequality of distribution also creates a resistance in the area of overdistended vessels against the easiest emptying of the heart, which resistance is one of the causes of its fatigue. The two essentials to the best action of a mechanical pump are abundant supply and free exit, and precisely the same principles apply to the heart-pump, which differs from the former chiefly in being compound and automatic, and in the character of the reservoirs of supply and outflow; the right auricle and left ventricle being the terminals of one loop of closed tubes, these two single pumps being valvularly connected respectively with the right ventricle and left auricle, which are the terminals of the other loop of closed tubes. In view of the simple physical principles just stated, it will readily appear that the proper working of the compound pump depends chiefly upon the state of the great complex loops of closed tubes.

These two loops of closed tubes are exceedingly complex in their branching and sub-branching, and their ultimate ramifications are microscopical and multitudinous, and they all have a quality, not imitable in a mere mechanism, of overdilation, and when so overdilated they have not power in themselves to return to their proper caliber. When a group of the microscopical tubes are overdilated they so press upon each other and the mesh of tissue among them that they practically form a dam through which the flow of blood is sluggish or arrested. Such a condition, or any abnormal condition, of any part of the two great circuits that interferes with the normal flow of the blood must in some degree affect the action of the heart, and the greater the degree or extent of the abnormal condition the greater must be the disturbance of the heart; also, the longer the continuance of the abnormal conditions of the vessels the more serious will be the impairment or fatigue of the heart. Is it not, then, manifestly irrational to ignore the cause of such impairment or fatigue and treat only the heart?

The true restoration of a proper supply to the heart pumps is not by infusing a saline solution (which only temporarily determines a greater volume in the peripheral vessels, which is soon lost by exosmosis and is not nutritious while it does last), but rather by the emptying of the overfilled vessels of their excess. This is not accomplished by the increased force of the heart's action from powerful stimulants, but it is accomplished by giving tone to the weak and relaxed fibers of the muscular coat of those overfilled vessels. As soon as this is accomplished, the heart, which had appeared almost paralyzed, no longer appears so and the fuller supply to the peripheral vessels gives the pulse a fair volume. Equalization of blood distribution should therefore be the prime object in treating the exhausted heart.

I think it is worth your while to consider for a moment another class of unstriped fiber whose defective states not infrequently determine fatality, namely, that of the muscular coat of the bowel. The mere suggestion of intestinal paresis will doubtless bring to your minds some unhappy experience. Even when there is not a complete paresis, an apathetic state of the bowel may give trouble enough, as when there is not time thoroughly to clean the bowels before a laparotomy, or when the directed and supposed preparation, by such clearing, has not been properly made.

I think it quite possible, from my experience with bowels, that the presence of old fecal matter may have more to do with unsuccessful or unsatisfactory surgery than is always appreciated. In a case to which I gave exceptional study daily for months, I demonstrated that the subject was literally packed with old fecal matter, notwithstanding his assurance that his bowels were "all right" and that they moved every day. Although I secured from two to eight movements daily, and also gave three or four enemas each day, it was three weeks before I succeeded in emptying the ascending colon, and it was only after ten weeks of daily heroic treatment that we ceased to see, in some of the stools, old fecal matter.

In another case similar treatment finally brought away quantities of impacted bran, the subject having formerly used bran bread as a laxative, but at the time she came under my care it had been two years since she had eaten bran bread. Two days before she came to me she had had a curettage of the womb, and within an hour after the operation acute mania developed, which was the most extreme in all my experience and subsided only after three years of the most energetic treatment that I ever gave in any case.

I once saw a famous surgeon, doubtless personally known to every one of you, operate for a supposed intussusception, but which he found when he opened the abdomen was simply fecal impaction, and the subject died a few days later.

Such conditions could have resulted only from deficient tone of the unstriped fiber of some portion of the bowel, not alone of the colon, but also of the small intestine. It is easy to see how such states, even of markedly less degree than those related, may entail grave consequences when associated with abdominal, pelvic or head operations.

There are many other things associated with general or special surgery of which I would like to speak, but I have already imposed upon your patience. I will, therefore, as briefly as I may, refer to some methods of correcting defective unstriped fiber. Of these there are several, most of them, however, applicable only to special and limited areas.

1. *Massage.*—When general physical exercise (which, in health, is the best promotor of good circulation) is prohibited by the state of the subject, massage is the most potent substitute that may be applied and, even in surgical cases, it has many appropriate applications.

2. *Dry Cupping.*—In all my armamentarium there

is no other mechanism for which I have more profound respect than for my improved dry cups, exhausted with an air pump and closed with a stopcock. I find frequent use for them to relieve internal congestions and to modify internal inflammations by withdrawing to the surface considerable quantities of blood which relieves temporarily the distended vessels and further, by the partial emptying of them and the reduction of the internal pressure against them, their weak muscular fibers are permitted to contract, which they could not do against the former pressure. After such contraction they have a power to hold against subsequent pressure, which they did not have in their more greatly stretched state. In addition to this, there is the very great damage to the vessels of the skin, when the cups have been well exhausted, the repair of which damage detracts to some extent from the abnormal internal circulatory activities. For this measure, also, the surgeon will find many uses to aid in correcting the defective unstriped fiber of internal vessels.

3. *Cold.*—When the congested or inflamed area is near enough to the surface to be directly influenced by it, continuous application of cold will contract the dilated vessels. This and ergot were the two special elements of treatment used in the case of fracture of skull and concussion above related. When continuous cold is not appropriate, the momentary application of heat to the spine, followed immediately by cold (ice or cold water) is a most excellent tonic to the relaxed unstriped fiber, probably through its direct influence upon the unstriped fiber of the vessels of the vasomotor centers.

4. *Electricity.*—What I say on this subject refers especially to galvanism or the direct dynamic currents, which are essentially the same in their action. They differ materially from the interrupted forms, especially in their ability to store force in the subject, precisely as they do in the storage cell. I demonstrated this important truth in 1890, when the meter registered a current of fifteen milliamperes, flowing from the subject, reversely to the direction in which it had flowed into him, just as occurs with the storage cell. When you consider in connection with this that the force so stored is like the vital force, and that, when applied to any special part, it accomplishes what the vital force, if sufficient, would accomplish, you can see that it may sometimes serve you well. But it is especially as to its stimulation of the unstriped fiber that I would now speak, and the most important application for such purpose which the surgeon is likely to have is to the muscular coat of the bowel. I do not know of anything else that will act as surely or as promptly upon that class of unstriped fiber, the positive electrode being placed under the spine and the negative electrode over the abdomen. Do not assume that you have done all that is possible to develop activity of the bowels in intestinal paresis or apathy until you have made thorough applications of the constant current.

5. *Ergot.*—The only medicament of which I know that has a tonic effect upon defective unstriped fiber, wherever situated, is ergot. As a stimulant to the muscular coat of the bowel I have found rhamnus frangula very effective, but I am not aware that it especially influences other unstriped fiber. What I say of ergot refers only to the hypodermic use of the drug and to its action upon pathologically weak or defective unstriped fiber. Of its action upon physiological unstriped fiber, I know no more than is obtainable from the books, and the subject is not important in this connection. The action of ergot upon pathological unstriped fiber is quite another thing and is of vast import, because of the multitude of its effective applications. I seriously question whether the therapeutic value of any special preparation of ergot may be satisfactorily determined by physiological experimentation, and I would determine such value only from clinical experience. The therapeutic value of ergot lies in its influence, which is probably chiefly direct upon the defective unstriped fiber with which it comes in contact or in proximity as it circulates through the ultimate vessels. Exactly what constitutes the change that is effected by it in such tissue I leave to those patient investigators who untiringly seek for the reasons of things.

I am assured by such an investigator that the state of exhausted or paralyzed unstriped fiber is very different from the state of the normal, and in the extreme abnormal conditions approaches the indefinite tissue state termed gelatinous. That there is an alteration of tissue would appear from the fact that recently exhausted unstriped fiber is quickly restored by ergot, while such tissue that has long been useless or deficient in function is restored only after protracted treatment.

While I have referred to a variety of abnormal states, I have endeavored to show that one single element is the essential basis of them all, namely, defective unstriped fiber. It follows therefore that a specific stimulant to such disordered tissue is applicable to each and all of the varied conditions mentioned. This specific is ergot; and I may add that the term "specific" is not here misapplied, as it so often is to other medication, because, however varied the final effects may be, they all occur in consequence of one, single, direct effect of the drug upon one, single species of muscular fiber, hence the action is truly specific. The application, in a given case of this or other therapy suggested, I must leave to you, referring you to my other papers* upon the subject, as the limit of this paper will not permit of further detail; but I would like, in closing, to make a few general suggestions.

1. At the very beginning of your use of ergot on the lines I have suggested bury, beyond resurrection, that hugbear that has followed you since you first heard the warning, "Beware of ergotism!"

2. Whenever possible to do so, *prepare* your cases with ergot, and thus avoid conditions that are annoying or serious rather than wait until such conditions have developed and then use the drug to correct them.

3. Use the drug freely enough to get the desired effects, yet be judicious and never reckless. While I have not seen ill-effects from my use of ergot, I can see no reason why overdosage might not do

*The Broad, Therapeutic Application of Ergot, *New York State Journal of Medicine*, September, 1902; Some New and Unusual Therapeutic Applications of Ergot, *Journal of the American Medical Association*, March 21, 1903; Ergot in Pneumonia, *New York State Journal of Medicine*, May, 1903; Uses of Ergot, *Brooklyn Medical Journal*, August, 1903; Ergot in Alcoholism, Morphinism, and the General Class of Drug Habit Cases, *New York State Journal of Medicine*, January, 1904, also *Medical News*, New York, March 5, 1904; Ergot in Typhoid Fever, *New York Medical Journal*, April 16, 1904; Ergot in Surgery, *New York State Journal of Medicine*, June, 1904; The Vital Relation of Unstriated Muscular Fiber to Pneumonia, Typhoid Fever, and Influenza, and Suggestion of Means to Correct Its Defects, *Medical Council*, Philadelphia, June, 1904; Ergot in General Practice, *Journal of the American Medical Association*, August 27, 1904.

harm, or at least thwart the object for which it is given.

4. Use ergot only *to correct defective unstriped fiber* and you will not be as disappointed as if you used it to "tone" unstriped fiber.

5. Always use ergot hypodermically.

6. Be sure that solution, syringe, and skin are sterile.

7. *Take care of the defective unstriped fiber,* and you may feel assured of the greatest safety in anesthesia, of relief from shock, of freedom from pain, or its modification, of avoidance of inflammation and of repair of the injured tissues, and your patients may also be assured that many, if not all, things else will be added which make for comfort and general well being.

LARGE TUMOR OF THE LARYNGOPHARYNX REMOVED BY SUBHYOID PHARYNGOTOMY.*

By WALTER F. CHAPPELL, M.D., M.R.S.C. Eng.,

NEW YORK.

A BRIEF history will be given of the patient on whom the operation of pharyngotomy was performed. Johanna, Austrian, aged 51. Mother died at 82 of asthma. Father still living at 91. When 18 Johanna developed a short, dry cough which persisted for some years, and was accompanied by considerable expectoration. At 36 she had a severe attack of grippe lasting three months and leaving her voice hoarse. A year later her last child was born, and this was followed by a temporary improvement in her hoarseness.

At 45 her breathing became slightly labored during the day, but at night when she was asleep it was much worse and soon became so bad that people living in the same house thought she was in danger of suffocation. These symptoms gradually increased, and the patient and friends thought she had asthma. A physician saw her once, but she did not visit him again, owing to the belief that she had incurable asthma.

Two years ago she began to choke on particles of food, and occasionally vomited a meal. Her breathing became more embarrassed, and she slept only at intervals at night; as a result she began to feel weak and would fall asleep during the day and even during a conversation. During the last few months she was awakened every morning with a severe headache and dizziness, which passed away after she was up. I saw Johanna on November 29 for the first time.

A laryngoscopic examination revealed a large mass of grayish-blue color completely filling the laryngopharynx. It pressed the epiglottis forward against the root of the tongue, laterally it touched the pharyngeal wall, and posteriorly the postpharyngeal wall extending downward some distance. In fact, it was difficult to understand how the patient could breathe or take nourishment. The surface was covered with large, tortuous vessels, which seemed to spring from a common origin on the left side near the posterior part of the ary-epiglottic fold and spread out like the ribs of an open fan over the surface of the tumor, as shown in figure 1. No part of the larynx was visible, and there was no external evidence of the large intralaryngeal growth.

The respiration was so much impeded at all times that it was considered unsafe to allow the patient to remain in a condition which might prove fatal at any moment. She was admitted to the Manhattan Eye, Ear, and Throat Hospital, and a low tracheotomy was performed under local anesthesia on November 20. The difficult breathing was immediately relieved on the introduction of a tracheal tube, and more nourishment could be taken with much less effort and discomfort. No bronchitis or other unsatisfactory symptoms followed the tracheotomy, and within a week the patient was well.

On December 28 the throat and tumor were thoroughly cocainized and an effort made to engage the growth in the loop of a cold wire snare. It was then discovered that, while the pedicle was not over an inch in width and diameter, several adhesions, such as shown in figure 2, kept the tumor somewhat firmly in place. It was also found that the posterior end of the tumor extended down the esophagus for some distance. It was suggested by some who were present at the

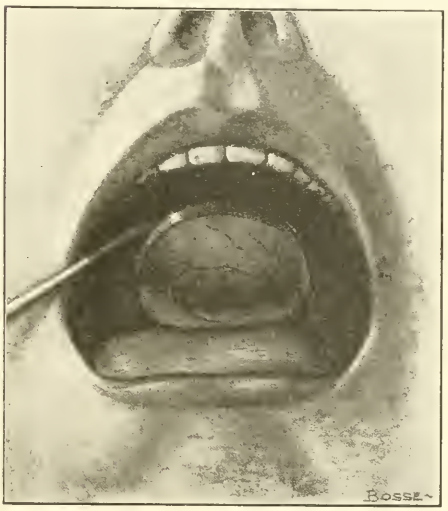

PLATE I.

examination, that the tumor was a cyst, but the introduction of a curved knife proved it to be solid and very vascular. An external operation was then advised.

On January 4, assisted by Dr. Harmon Smith and Dr. John E. MacKenty, I performed a subhyoid pharyngotomy. The steps of the operation need hardly be repeated in detail before this audience.

On opening the thyrohyoid membrane and pulling the epiglottis forward the tumor came into view. Its position and appearance is remarkably well shown in figure 3, which was drawn by Mr. K. K. Bosse from sketches and notes taken at the time of operation. The pedicle was found close to the left ary-epiglottic fold, and from appearances seemed to consist mostly of large vessels. A black silk ligature was used in tying the pedicle, as it was feared anything else might not hold during vomiting or swallowing. Later these silk ligatures had to be removed through the mouth, and I believe chromicized gut would have answered every purpose.

*Read before the American Laryngological Association at Washington, May 9, 1907.

It was found that the tumor was covered with a thick, vascular capsule, which was incised at the right end, and the growth removed. The capsule was cut off at the pedicle and bled very little. The larynx and esophagus were examined and found to be in their normal condition. The thyro-

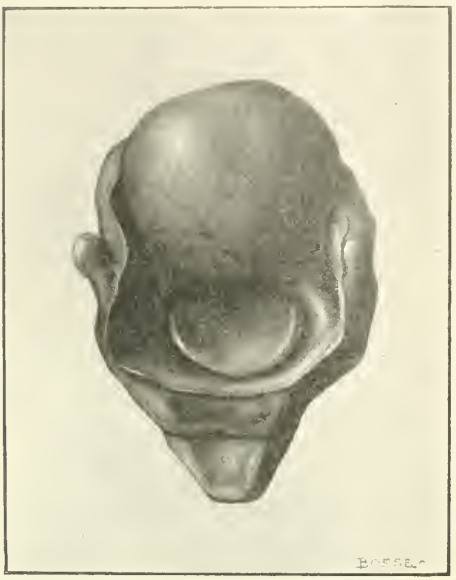

Plate II.

hyoid membrane, muscular and cutaneous tissues were stitched together separately, and the patient returned to bed.

The tumor was smooth, irregular in shape, weight 20 grams after it had been in formalin, circumference 4½ inches. The tumor on microscopic examination was found to consist of fibrous tissue, very moderately supplied with nuclei and round cells.

Absolute rest of the organs of deglutition was ordered and nutritive and saline enemata were given. Considerable blood was coughed out of the tracheal tube for twenty-four hours, but then ceased. On January 10 as much sterile water was ordered as the patient wanted, and was swallowed fairly well, although some came through the tracheal tube. On January 14 four ounces of peptonized milk was given by mouth, but not retained. A few days later broths and milk were given by the mouth, but a great deal ran out through the tracheal tube and caused a good deal of coughing. The patient began to look badly; a small fistula formed in the right angle of the wound and soon another formed in the left angle. All fluids by the mouth were discontinued and the fistulæ closed at once.

Nasal feeding through a tube was ordered January 25, and all rectal nourishment discontinued. A decided improvement set in; but some joint pains and slight redness of the gums showed that the feeding had not been all that was required and that the patient had a mild attack of scorbutus. Plenty of orange juice, through the nasal tube, soon relieved the scorbutic condition.

On February 15 the tracheal tube was taken out, and on the 27th the nasal feeding was discontinued. Liquids were swallowed well, and some solid food was given on March 1. Although some coughing followed each meal, the diet was not again changed.

The patient was shown at the Academy of Medicine about this time and caught a cold which was followed by some bronchitis, keeping her in bed over two weeks. On March 30 the patient left the hospital.

Remarks.—Laryngeal symptoms developed in girlhood, but no evidence of a growth was apparent until many years later. The growth of the tumor was slow, and implicated first, respiration, and later deglutition. It seems remarkable that so large a growth could exist for so many years without causing any great distress. The patient's health was remarkably good at all times, and she seems to have suffered very little.

The tracheotomy and major operation were well borne. The temperature for ten days after the operation for pharyngotomy never rose above 100° F., in fact beyond a slight cough the patient had no bad symptoms until she began to take milk and broth by the mouth; about one-half of these fluids passed down the esophagus and the balance entered the larynx, most of it passing out through the tracheal tube, but some trickled down the trachea and large bronchi. Quite a sharp attack of tracheitis and bronchitis followed, but soon ceased when nasal feeding was instituted. Rectal and nasal feeding for at least six weeks following the operation would have prevented some of our troubles.

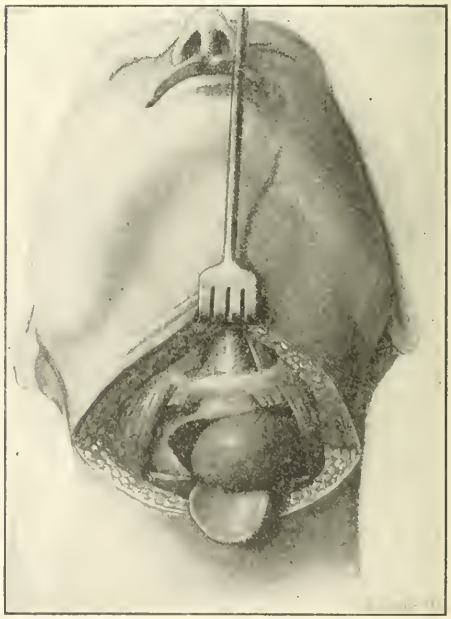

Plate III

After the tracheal tube was removed solid food had to be taken slowly, as there was some difficulty in swallowing, due to considerable swelling of the left arytenoid. This swelling was caused by the irritation of one of the silk ligatures already spoken of. The removal of the ligature was fol-

lowed by a marked improvement in swallowing. For some weeks later deglutition was somewhat difficult, but it constantly improved, and at the present time swallowing is perfect, and the patient restored to all her normal functions and a good state of health.

It was a mistake to have overlooked the possibility of the occurrence of scorbutus, and when artificial feeding is continued for so long a period the fruit acids should certainly be administered.

The patient was kept in a large single room in the hospital, but she was so depressed that we removed her to a ward with other patients, and she immediately became more cheerful and her condition generally improved.

In looking over the literature on this subject some eleven tumors of a similar nature have been reported.

One took its origin from the epiglottis, another from the ary-epiglottic fold, another from the anterior part of the commissure a little left of the median line, another from the anterior part of the larynx below the vocal cords, another attached by a broad base to the anterior commissure and the anterior third of the right vocal cord, another occupied the whole left half of the larynx, the left ventricular band, and the left ventricle, and nothing could be found of the left vocal cord, the growth extended out of the larynx into the left side of the neck and was partly intralaryngeal and partly extralaryngeal.

One tumor was removed by a subhyoid pharyngotomy, but the patient died seven days after, the operation with metastatic abscesses in both lungs. A lateral external operation was successfully performed in two cases. One case died by suffocation without an operation being attempted. In the other cases the tumors were removed by intralaryngeal operations.

The size and adhesions of the tumor I have presented demonstrate that it could only have been removed by a subhyoid pharyngotomy, and I believe a great part of our success was insured by the tracheotomy preceding the major operation.

Massage of the Heart in Suspended Animation.—Ricketts says that sub-diaphragmatic transperitoneal cardiac massage is supposed to have been first done by Starling and Land in 1902. The heart is grasped with the hand, with the diaphragm intervening. Eighteen cases have been treated in this way, in eight of which the abdomen was deliberately opened for the purpose and in ten the abdomen had already been opened for other purposes; in three chloroform was used; ten not stated. In three the diaphragm was deliberately opened from below to massage the heart. Ten permanently recovered; eight died, but in five of which the pulsations were restored for a short time. —*Illinois Medical Bulletin.*

A CASE OF TYPHOID PERFORATION OF THE APPENDIX; OPERATION AND RECOVERY.*

[By HENRY MOFFATT, M.D.,

YONKERS, N. Y.

ATTENDING SURGEON TO ST. JOSEPH'S HOSPITAL, YONKERS, AND CONSULTING SURGEON TO THE WESTCHESTER COUNTY ALMSHOUSE, AT EAST VIEW.

The case I propose to present to you to-day seems to me sufficiently interesting to serve as a text for some remarks upon a subject which, I think, has not thus far received due consideration by either surgeons or general practitioners. Briefly, the history of the case is as follows:

Miss L——, age seventeen, single, an epileptic, was treated by Dr. Madden of Ossining, N. Y., from March 20 to April 20, 1904, through a well-defined attack of typhoid fever, with typical temperature curve, diarrhea, meteorism, and a plentiful display of rose spots over the abdomen and chest. Her convalescence was rapid and good—though upon careful questioning later, she stated that there was at all times some pain over the right iliac region, to such an extent that it was uncomfortable to lace her clothing. Two weeks after her convalescence had set in she was suddenly attacked with symptoms of acute appendicitis—severe pain and tenderness over the region of the appendix, fever, rapid pulse, vomiting, etc.

When Dr. Madden called me to see the case, which was within twelve hours of the onset of the symptoms, there was a well-marked tumor in the right iliac region, in addition to the symptoms given above. I urged immediate operation—had the patient removed to the Ossining Hospital and operated upon her there at the earliest possible moment. Drs. Madden, Minor, Byington, and Irvine were present.

There was a large abscess firmly walled off by protective adhesions, containing a large amount of fetid pus. The appendix was readily exposed and a perforation was found at the proximal end an eighth of an inch from the cecum. The whole appendix showed signs of inflammatory changes. The muscular walls were swollen and indurated and the mucous lining was thickened. The perforation presented the appearance of a typical typhoid character, oval in shape, with overhanging edges. The appendix was removed and the abscess cavity thoroughly drained. The patient made a good recovery, though her convalescence was somewhat long and retarded by some further pocketing of pus.

Though this complication of typhoid fever has been recognized for many years, it is remarkable how little attention has been given to it till within a very recent date. The first reference to a perforation of the appendix occurring during typhoid fever, as far as I can find, is made by an Italian, Carlo de Vecchi, in 1848, who relates a case of such a perforation found at the autopsy in a man dying on the seventh day of typhoid fever. Heschl, in 1853, reported fifty-six cases of typhoid perforation, with eight in the appendix. Buhl, in 1854, gives an account of three such cases, and three years later Sands also presented to the New York Pathological Society a case in which the perforation was found at the autopsy, and he described the condition at length in an article in the *American Medical Monthly*, 1857. In 1867 Morin reported sixty-four

*Presented at a meeting of the Westchester County Medical Society, January 15, 1907.

cases, with twelve in the appendix. Notwithstanding these well-authenticated cases, none of the text books make any reference to such a complication in typhoid fever.

James H. Hutchinson, in his exhaustive article on typhoid fever, in Pepper's System of Medicine, 1885, makes no mention of this. Osler in his edition of 1893 makes no mention of it; but in his late edition quotes a series of cases, reported by Hector McKenzie in the *Lancet* of 1903, where out of 264 cases of perforation 232 occurred in the ileum, 22 in the jejunum, and 9 in the appendix.

The only allusion to the possibility of this condition that I can find in Strümpel, 1891, is as follows: "Perforation generally takes place in a coil of the lower part of the small intestines, with marked relative frequency in the right side of the pelvis, seldom in the vermiform appendix or in the colon."

As the appendix, with all its powers of evil, began to attract the attention of both surgeons and pathologists, this condition has gradually gained consideration. Fitz, in the *Boston Medical and Surgical Journal*, 1891, published 167 cases of perforations, with 5 in the appendix. Hawkins, in the *Lancet*, July, 1893, gave the analysis of the seat of perforation in 72 post mortems in typhoid—61 ileum, 5 in the colon, 3 in the cecum, and 3 in the appendix.

Dr. Bontecon of Troy, in the *Journal of the American Medical Association*, October 17, 1887, reports an operation for perforation of typhoid ulcers in which he found a perforation of the appendix as well as one of the ileum, ten inches from the colon. Schell, in the *New York Medical Journal*, April 20, 1895, said: "Next to the ileum, the cecum and the vermiform appendix are the most frequently altered by ulceration and gangrene in typhoid fever."

But among all the writings on appendicitis little or no systematic treatment of this subject can be found till 1905, when Howard Kelly brought out his beautiful and exhaustive work. Here this whole subject is most thoroughly handled and given that prominence which the gravity of the condition demands.

When we consider the character of the mucous lining of the appendix, supplied abundantly with solitary and agminated glands, crypts of Lieberkuhn and lymph nodes, and when we know that the most frequent seat of typhoid inflammation is at the lowest portion of the ileum and near the ileocecal valve, we would readily be led to infer that an involvement of the appendix in this infection would not be an infrequent occurrence. Numerous observers have shown this to be a fact. O. Hoppenhaussen in the *Revue de la Suisse Romande*, 1899, gives a report of thirty autopsies in typhoid fever, and finds that in every instance the appendix was affected to a greater or less extent, varying from a mere hyperemia of the mucosa to an extensive ulceration.

Kelly has collected thirty cases in which the condition of the appendix during typhoid fever was demonstrated by operation or autopsy, in most of which, he states, there had been symptoms of appendicitis during the course of the typhoid. "In five cases the microscope gave evidence of typhoid ulcers within the appendix; in one there was ulceration without perforation; in ten, perforation; in one, appendicitis with abscess; in four a simple congestion, with a perforation situated in the ileum; in the remaining cases adhesions, flexions, or obliterative changes." H. Christian in 119 autopsies on typhoid patients at the Johns Hopkins and the Boston City Hospitals found nineteen showing distinct inflammatory changes in the appendix.

These cases seem to prove conclusively the existence of true typhoid appendicitis. There is also a possibility of a simple appendicitis occurring during the course of a typhoid fever. Kelly, however, says of this form of disease, "I fail to find any satisfactory instance of simple acute appendicitis occurring during the course of typhoid fever." He admits that a latent or chronic appendicitis may be roused into activity during typhoid fever in several different ways.

Dr. L. W. Hotchkiss of New York related to me only a few days ago a case in which he had removed a perforated appendix during typhoid fever, in which the cultures carefully made failed to show anything more than acute appendicitis. Where there has been a previous attack of appendicitis and the appendix is acutely flexed and bound down by adhesions, we can well imagine there would arise serious complications if this organ should become the seat of typhoid inflammation. Even if it was not involved, the distention of the intestines in the immediate neighborhood would be likely to cause intense discomfort and even lead to injury to the parts affected.

There is still another condition to be considered, namely, post-typhoidal appendicitis, and it is in this class that I must place the case I have reported. In these cases the question arises: Is the subsequent appendicitis due to the necrotic remains of the typhoid inflammation retained in the appendix and waiting an opportunity to set up an acute attack, or have the healing ulcerations of typhoid so contracted the caliber of the appendix as to produce a retention of the discharges and favor a subsequent acute attack? Is it not possible that a case may be due to a combination of these conditions? Again, could it not be due to a small perforation occurring during the typhoid, rapidly and firmly walled off by protective adhesions which at a later date rupture and produce a larger abscess or even a diffuse suppurative peritonitis?

I am inclined to consider the possibility of my case being in this class, from the large size of the abscess and the fact that the pain and tenderness persisted in the region of the appendix during her convalescence up to the date of her sudden attack.

We see such cases frequently in other forms of appendicitis, and I am inclined to believe that this is a reasonable explanation of the symptoms in this case. In this class Kelly reports only two cases, but refers again to the figures of O. Hoppenhausen, who shows that out of 748 cases thirty-six cases of appendicitis showed previous history of typhoid fever, varying from six months to forty-eight years.

Bull, in the *American Medical Recorder* of March, 1893, reports that in twelve cases of relapsing appendicitis, three gave history of previous typhoid fever, one eighteen years previously, one four years previously, and one three years previously. The case referred to by Walker Schell in 1895 was one in which he operated successfully upon a case of appendicitis four weeks after apparent recovery from typhoid fever, and he concludes with the remark that "the relation of typhoid fever to anatomical changes in the appendix has not been sufficiently emphasized."

Whether the previous attack of typhoid had any causal relation in all of these cases, it is impossible to say. But when we consider the possibility of the crippling of this organ by ulceration and contractions due to the typhoid inflammation, it would seem likely; and I agree with Kelly that it would lead to more definite knowledge if all our hospital records of cases of appendicitis should include a note as to any previous attack of typhoid fever.

If, as it has been shown, the occurrence of appendicitis during typhoid fever is not so common, it is certainly of the greatest importance to differentiate the two conditions. This is by no means easy. The pain, tenderness, and distention of the abdomen so often marked in typhoid fever in the region of the ileocecal valve might easily mislead us. But when, in addition to the symptoms given above, there is suddenly added muscular rigidity over that region, together with vomiting and a sudden increase of fever, we must suspect an involvement of the appendix. But often the question of diagnosis between these two diseases is imperative from the outset. This may be especially difficult when there may have been previous appendicitis and the earlier symptoms of the typhoid may be attributed to the old condition, especially when the distended bowel sets up pain in that region by dragging on old adhesions.

Bearing upon this point, Richardson, in the *Boston Medical and Surgical Journal*, January, 1902, says: "The surgeon must always be on his guard lest he fail to recognize typhoid, not only in its ordinary forms, but in its unusual and atypical forms, and subject his patient to an operation which, even if apparently made necessary by the clinical evidence, is entirely unjustified by the pathological findings." Also: "In acute abdominal lesions, considered from a surgical standpoint, four symptoms have especial weight, viz., pain, tenderness, muscular rigidity, and fever. No lesion of the appendix sufficiently extensive to affect the peritoneum can possibly exist without pain, tenderness, muscular rigidity, and fever. Let any one of these symptoms be absent and doubt as to the existence of acute appendicitis arises." In such cases, we must examine by every means in our power, for the presence of typhoid. As, for instance, whether there is any history of a typhoid epidemic in the neighborhood, or whether there were any prodromal symptoms. A careful blood count is of importance. The leucocytosis in typhoid is always low. This is a more reliable sign than the Widal test, as the latter test often fails to develop before seven to ten days, or even later. It should, however, be tried, for when it gives a positive reaction the question of diagnosis is settled.

The symptoms of perforation of the appendix in typhoid are similar in great measure to perforation in other portions of the intestines. When this accident happens, there is apt to be sudden acute pain, accompanied by a fall in temperature. This latter symptom occurs in case of hemorrhage, but without the pain. It is to be noted, however, that hemorrhage often precedes the perforation. Later the patient sinks rapidly into a condition of collapse, followed by symptoms of acute peritonitis.

The question of operation in these cases is a grave one, especially as we know that all operations in the later stages of typhoid fever have a high mortality. In true typhoid appendicitis experience thus far seems to point to a conservative treatment of such cases as are not of the gravest character, and do not show distinct symptoms of perforation. Kelly advises that, "in the absence of exceedingly urgent symptoms, the best general rule is not to operate. The clinical history of the collected cases seems to show that with the rarest exceptions there is no more reason for operating upon a true typhoid appendix than there is for cutting down upon the ileum and excising the affected Peyer's patches."

J. B. Murphy concurs in this opinion and says that typhoid appendicitis should not be operated upon unless there is a perforation. All will agree that a perforation demands an immediate operation, whether of the appendix or of any other portion of the intestinal tract. Post-typhoid cases should be treated as any other case of acute or relapsing appendicitis. Here operations should have no higher mortality than in appendicitis from other causes. When the operation is decided upon, it should be done rapidly, thoroughly, and with the strictest aseptic precautions, the surgeon remembering to inspect other portions of the intestines in the region of the cecum with the possibility of discovering other perforations.

The perforation of the appendix is treated as any other perforation of this organ, namely, by excision of the affected appendix. Perforations of the cecum or of the ileum in the region of the cecum should be rapidly closed by Czerny-Lambert sutures if possible. In case of rapidly approaching collapse, with a large perforation, it may be necessary to attach the affected portion of the bowel to the abdominal wall, making an artificial anus, which can be closed at a later date if the patient survives.

139 Park Avenue.

PARAPLEGIA CAUSED BY AN ANEURYSM OF THE ARCH OF THE AORTA.*

By BOND STOW, A.M., M.D.,

BLACKWELL'S ISLAND, NEW YORK.

PATHOLOGIST TO THE METROPOLITAN HOSPITAL.

Thomas V., colored, 39 years, laborer and painter. Admitted to Metropolitan Hospital, New York City, December 12, 1905.

Family history negative. Immoderate tobacco chewer and drinks beer and whisky to excess. Measles and chickenpox in childhood. At 17 had gonorrhea, followed by gonorrheal arthritis of the left knee and ankle. At 18 had hard chancre, followed by secondary lesions of syphilis.

Present illness began about two years ago, since when his chief complaint has been repeated paroxysmal attacks of coughing, accompanied by an excessive amount of a thin serous, watery, foamy expectoration. Repeated paroxysmal attacks of intense pain in the left upper thorax posteriorly between scapula and dorsal vertebræ. Always more or less dull pain over the upper dorsal vertebræ between the scapulæ. Occasionally complains of severe pain over the precordial region. Has paroxysmal attacks of dyspnea accompanied by an alarming cyanosis; dysphonia, the voice being rough and rasping in character; at times complete aphonia; dysphagia occasionally present, although the patient never complained of pain upon swallowing; at times there was severe nausea, generally after the taking of food. Obstinate coprostasis. Pulse was irregular and weak, ranging between 72 and 96. Temperature ranged between 97° and 98° F. Respiration varied

*Read before the Section on Medicine of the New York Academy of Medicine, May 21, 1907.

between 20 and 44 per minute. Complete loss of motion in lower extremities. Sensory disturbances negative. Likewise trophic conditions. No incontinence of urine nor feces. Reflexes exaggerated. Slight atrophy from disuse of lower extremities. Apex beat in fifth interspace reaching the midclavicular line. Remaining heart boundaries not enlarged. There were no abnormal cardiac murmurs. The right radial pulse was felt sooner than the left. There was also a retardation of the crural pulses.

There was a retraction of the chest wall at the left apex and marked dullness on percussion in the upper half of the left thorax, both anteriorly and posteriorly. Auscultation posteriorly between the scapulæ gave a harsh, rough, rasping, systolic murmur. Coarse mucous râles were heard at the bases of both lungs.

Laryngeal examination showed a paralysis of the left vocal cord.

FIG. 1.—Aneurysm of the descending arch of the aorta. A. Spinal cord in depth of aneurysmal sac exposed to view. B. Organized blood clot 31 cm. in diameter removed from the walls of the aneurysmal sac. C. Thoracic aorta immediately below the aneurysm, showing a therosclerotic patches. D. Bodies of third, fourth, and fifth dorsal vertebræ destroyed by pressure atrophy from aneurysm. E. Lowest depth of aneurysmal sac. F. Opening from surface of arch of aorta into a small secondary aneurysm that connected with the primary aneurysm. H. Esophagus, showing the outer wall firmly adherent above to the aneurysm. I. Posterior wall of the right thoracic cavity near vertebræ. J. Posterior wall of the left thoracic cavity.

Uranalysis was negative.

Sputum analysis showed no tubercle bacilli.

Diagnosis of an aneurysm of the arch of the aorta with probable erosion of the upper dorsal vertebræ and compression of the spinal cord.

The man died December 7, 1906. The autopsy was performed 20 hours after death. Post-mortem rigor present. Hypostatic congestion of the dependent portions of the body. Pupils both equally dilated 4 mm. Muscular and subcutaneous tissues well developed. No edema present. No external marks on the body. Peritoneum smooth, glistening, and transparent. Mesentery and mesenteric glands normal. Peritoneal cavity contained a small amount of a pale, clear, amber-colored transudate. The abdominal organs were in normal situs. Diaphragm on the right side was at the level of the sixth interspace; on the left side at that of the fifth interspace.

Both pleural cavities contained about 500 c.c. of a pale, clear, amber-colored transudate. The pleura covering the upper half of the left lung was firmly adherent anteriorly and posteriorly to a large aneurysm of the arch of the aorta, as well as the thoracic walls, showing evidence of an old pre-existing pleuritis. The upper lobe of the left lung was atrophic in consequence of compression from the aneurysm. The lower lobe showed extensive congestion and edema. The right lung appeared about normal in size and consistency, and in its lower lobe showed extensive congestion and edema. There was nowhere in either lung any evidence of tuberculosis or of a previously existing pneumonia. The pericardium was smooth, glistening, and transparent. The pericardial sac contained about 200 c.c. of a pale, clear, amber-colored transudate. The left ventricle was firmly contracted. The right ventricle was collapsed. The coronary arteries showed arteriosclerosis. The blood-vessels on the surface of the heart were partially emptied. The left ventricle measured at its apex 1 cm. and at its base 1½ cm. The ventricle was not dilated. The left auricle measured 2½ mm. The right ventricle measured 3 mm., and the right auricle 1 to 2 mm. The endocardium was smooth, glistening, and transparent. All valves appeared normal. At the beginning of the arch of the aorta there was present endarteritis chronica nodosa syphilitica. At the transverse portion and descending arch of the aorta, also in the thoracic and abdominal aorta, were numerous calcareous deposits. At the descending arch of the aorta there was a large aneurysm which extended downward a distance of about 10 cm., and which filled up the entire upper half of the left thorax. The aneurysm was firmly adherent to the posterior thoracic wall and the bodies of the upper dorsal vertebræ. The bodies of the second, third, fourth, and fifth dorsal vertebræ were partially or entirely destroyed by erosion laterally, so as to expose the spinal cord for a distance of about 5 cm. The aneurysmal sac was filled with a large well organized firm clot that measured 31 cm. in circumference (see illustration).

The aneurysm protruded into the right pleural cavity, compressing both the esophagus and trachea, and pressing them to the right.

Examination of the remaining organs of the body proved negative.

Gross section of the cord above and below the point of compression showed nothing abnormal.

Microscopical sections of the cord above and below the aneurysm also showed nothing abnormal. The multipolar cells were well developed and their nuclei stained normally. There was no evidence of any changes in any of the main tracts of the cord.

The diagnosis was: Aneurysm of the descending portion of the arch of the aorta, with erosion of the bodies of the second, third, fourth, and fifth dorsal vertebræ.

Concentric hypertrophy of the left ventricle. Chronic endarteritis nodosa syphilitica, with calcareous degeneration of the aorta. Passive congestion and edema of the lower lobes of the lungs.

Pressure atrophy of the upper lobe of the left lung. Old pleuritis of the left lung. Immediate cause of death, hemorrhage from rupture of the above mentioned aneurysm.

Remarks.—Aneurysms of the arch of the aorta naturally follow the line of least resistance, and thus usually cause destruction of the sternum and anterior thoracic wall. In the present case the previous pleuritis had caused a fixation of the aneurysm to the dorsal vertebræ and posterior thoracic walls, with consequent destruction by pressure atrophy of these parts.

VAGINAL IMPLANTATION OF ADENOCARCINOMA OF THE UTERUS—BLOOD METASTASIS IN RECURRENT CARCINOMA.

By GEO. W. KAAN, M.D.,

BOSTON, MASS.

PROFESSOR OF CLINICAL GYNECOLOGY, TUFTS COLLEGE MEDICAL SCHOOL; ASSISTANT SURGEON, FREE HOSPITAL FOR WOMEN, ETC.

In his book upon Cancer of the Uterus (p. 414), Cullen speaks of having seen only one case of adenocarcinoma of the vagina, secondary to adenocarcinoma of the body of the uterus; and says that such metastases have rarely been reported, and that the extension of the growth to the vagina is an unexpected complication, inasmuch as the lymphatics from the uterus do not pass toward the vagina. He further remarks that there are two ways in which this secondary involvement may occur: the first by implantation, the carcinoma cells from the body finding their way down through the cervix, clinging to the vagina, and there developing; the second through a backward flow of the lymph (*rückläufige metastase*). Fischer, reporting a case, inclined to the implantation view, but Cullen thinks it much more probable that in the cases cited the extension had taken place along the lymphatics, as there was no evidence of injury to the vagina which would have given the cancer cells a satisfactory location for development; furthermore, it is the degenerate and necrotic cells that are cast off, and not the living, active ones. Later in his book (p. 663) he refers to two cases of implantation during vaginal hysterectomy. Here there was recurrence in the scars where the vaginal walls had been incised to get more room during the operation; there was no recurrence at the original site. In these cases Cullen feels that metastases cannot be absolutely excluded.

Roberts ("Gynecological Pathology," p. 245) says that metastatic deposits are rare in cancer of the uterus. If they occur at all, the liver, lungs, and kidneys are mostly affected. Winter found in 202 cases of recurrence only nine real examples of metastasis. The lymphatic vessels of the vulva and the lower third of the vagina go to the inguinal glands; those from the middle third of the vagina and cervix to the iliac glands at the bifurcation of the common iliac arteries; those of the body and fundus pass along the broad ligaments with the ovarian vessels to the lumbar glands below the kidney.

Gebhard ("Pathologische Anatomie der weiblichen Sexualorgane," p. 546) differentiates implantation from "continuation," the former being in those cases where there is a separation by sound tissue between the cancer of the body and that of the vagina. He thinks we are forced to the conclusion that cells from the primary growth in the body of the uterus flow with the secretion and settle upon the eroded vaginal surface. Therefore if there is found in the vagina a malignant adenoma or adenomacarcinoma, then the interest of the patient demands a search for the primary condition in the corpus uteri.

In connection with the above I wish to report two cases of vaginal implantation of adenocarcinoma and one case of blood metastasis in recurrent pelvic carcinoma.

Case I.—I saw an unmarried lady of about sixty years in February, 1897, when I removed a polypoid fibroid of the uterus which had been forced through the cervical canal and was held by a pedicle. The fibroid was about the size of a lemon, and there was no apparent laceration of the cervical tissue. I saw her later, in February, 1903. She had been having a slight show. Examination showed the cervix irregular in outline, with a fungoid growth the size of a quarter dollar on the posterior vaginal wall opposite the external os. The abdomen was opened, but the uterus was found with the growth already largely invading the wall of the bladder. This condition, together with that in the vagina, made any attempt at a radical operation inadvisable. The growth in the vagina was extirpated and sent to the Free Hospital for Women laboratory for examination by Dr. Graves. The disease progressed slowly, the patient living for two years and three months. There was no breaking down of tissue through the vagina, nor was there any recurrence at the site of the extirpation of vaginal tissue.

Following is the pathological report: "February 12, 1903. Piece of tissue 1 1-2 cm. long by 1 cm. wide, rather soft. Microscopical examination shows the muscular wall of the vagina infiltrated by glandular masses growing in an atypical form. In places the gland arrangement is lost and the type approaches more the squamous variety. There is erosion of the surface with considerable inflammatory infiltration in places. The squamous epithelium is thickened and very vascular. Blood-vessels have greatly thickened walls. Many of the cells have large mucoid vacuoles. Diagnosis: Adenocarcinoma of the vagina (secondary)." There was no autopsy in this case.

Case II.—This patient was seen in February, 1903. An unmarried lady, fifty-two years of age, reported flowing for twelve years. At the age of thirty she had a similar spell of flowing lasting for two and a half years. The examination showed a large uterus the size of two fists, with a growth about the size of a quarter dollar on the right lateral vaginal wall close to the cervix. The fungoid growth had much the same feel and appearance as that in the first case. The patient had mitral insuf-

ficiency, and had a severe hemorrhage when making her arrangements at the hospital for a bed. The operation was delayed for more than a month, but the flowing could never be stopped entirely, and a hysterectomy was done as a last resort. The heart could not stand the strain and she died. Dr. Graves' record is: "Very large uterus (three times normal); soft, thickened muscular wall. Section shows endometrium to be occupied by necrotic mass of fungoid tissue, having fine, delicate, finger-like processes. The growth seems most prominent in a circular portion of the posterior (?) surface of canal, about the diameter of a silver dollar. The process does not seem to have invaded the muscular wall to any considerable extent. Microscopic examination shows the masses of necrotic tissue to be made up of rapidly growing epithelial cells, which occasionally show a definite glandular tendency. Diagnosis: Adenocarcinoma of the body of the uterus."

These two cases, one supplementing the other, point to "implantation" in the vagina as the reasonable conclusion. Neither a backward flow of lymph nor the blood current would be likely to present the lesion in two cases in so nearly the same location; whereas a discharge from the uterus through the cervical canal would impinge on the posterior vaginal wall opposite the os externum just where these vaginal growths were found.

Case III.—The case of blood metastasis rests upon the post-mortem examination. The patient, about forty years of age, had a hysterectomy for cancer of the cervix. This was in the spring of 1905. In August, 1906, she developed a cough. A few months later she had signs of a pelvic recurrence, resulting in pronounced edema of the left leg and then of the right leg. The report of the post-mortem examination made by Dr. Leary of Tufts' College Medical School is as follows: "Body of a woman of about forty years, well developed, fairly nourished. Both legs markedly swollen, reddened, and edematous. In median line of abdomen midway between the umbilicus and symphysis is a ragged linear scar 9 cm. long. Abdomen distended. Subcutaneous fat small in amount. Costal cartilages generally calcified in central portions. Pericardium normal. Heart of normal size; valves and cavities normal; muscle pale and flabby. Pleural adhesions, rather easily separated, are found attaching lung to chest wall over lower parts of both backs. The left chest contains about 300 c.c. of a bloody serous fluid. The lungs over region of adhesions, *i.e.* lower backs, show flattened, grayish-white, opaque masses of tissue varying from 0.3 to 1 cm. in diameter, occurring singly or in conglomerate masses, and limited in good part to the portion of lung just beneath the pleura. The lower lobe of right lung contains, in addition to masses along pleural surface, many large, solid nodules occupying most of the lower portions of the lobe. The largest nodule, 3 cm. in diameter, projects onto the pleural surface over the diaphragm. Lungs are otherwise normal. On diaphragmatic pleura, over left upper margin of right lobe of liver, and opposite large nodule in right lung, are three flattened papillary nodules, 0.5, 1x1.5, 1x1 cm., respectively, in surface area, and 0.5 cm. deep. Over parietal pleura on both sides, in region of adhesions, are a few scattered, small, flattened masses of new growth. Bronchial nodes enlarged; largest 3x2.5x 2 cm. On section, tissue of nodes is seen to be replaced by a grayish-white new growth, which is opaque in places, elsewhere translucent, and soft. Mediastinal nodes above bifurcation of bronchi are similarly enlarged.

"Abdomen. Intestines distended by gas. Omentum adherent to abdominal wall along region of scar. Firm adhesions also bind the ileum 30 cm. from valve in a U-shaped fold, not tightly constricted, however, to the tissues over sacrum below pelvic brim to the right. The sigmoid is bound in a similar fashion for 15 cm. of its length beneath the pelvic brim to the left. The hand in the pelvis meets a bridge-like, dense band of tissue crossing pelvis from side to side, firmly adherent to bladder in front, and leaving a wide space behind into which rectum can be followed. Pelvic contents removed with difficulty on account of a mass of tissue of pork-like density on left side of pelvis, and general retroperitoneal inflammatory thickening. The bridge of tissue described is dense, is thickest above vault of vagina, and shows a small abscess cavity in connection with the vault of the vagina on the left side, by an opening 0.4 cm. in diameter. The tissues along the pelvic wall to the left are dense and on section disclose several veins, including the internal iliac, which are filled with almost completely organized thrombi. The left external iliac vein is imbedded in dense inflammatory tissue, and is filled with an almost completely organized clot up to 4 cm. below the union with the right common iliac. Right external iliac is distended with currant-jelly clots almost to junction with left. On laying open inferior cava, the intima is seen covered by a ragged clot, opaque, rather dry, adherent to wall, leaving a small central lumen, and extending up to just below the entrance of the renal vein. The lower retroperitoneal nodes are swollen, gray, and soft. The upper retroperitoneal nodes, including the gastrohepatic nodes and the lower mediastinal nodes, are not enlarged.

"Liver not remarkable except for some slight opacity and increase in density in right lobe, to right of suspensory ligament on anterior edge. Organ generally soft, pale, showing markedly deeper color in center than peripheries of lobules. Gastrohepatic nodes not palpable. Spleen small, not remarkable. Kidneys large, soft, moist, some post-mortem changes in right. Marking normal. Capsule peels smoothly.

"Bladder distended with urine. Walls of normal thickness, except where adherent to band posteriorly; here the thickening is limited to the perivesical connective tissue; the muscle and mucous coat being normal. There is marked injection, with petechial hemorrhage of mucosa, about sphincter vesicæ. The orifice of right ureter is somewhat dilated, as is the ureter above orifice; but mucosa is smooth and normal to inspection. Intestines normal, except for adhesions noted. Aorta not remarkable.

"Diagnosis: Total extirpation of uterus. Recurrent carcinoma of pelvic connective tissue; of iliac, retroperitoneal, and mediastinal lymph nodes; of lungs and pleura. Obliterative endophlebitis of common, external, and internal iliac veins and pelvic branches. Thrombosis of inferior vena cava. Hemorrhagic cystitis. The absence of a continuous chain of glands in the retroperitoneal region and in the mediastinum leads to a belief that the lung processes originated through blood metastasis. Microscopical examination of the pelvic tissues shows invasion of the walls of the vein and arteries, although no penetration through the intima was discovered."

I will say in conclusion that methylene blue was

advised as soon as the recurrence was recognized, but was persistently declined by the patient; trypsin was injected later. The autopsy shows that the case was wholly unsuitable for any such treatment.

419 Boylston Street.

HEART DISEASE AND BLOOD PRESSURE.

PHYSIOLOGICAL REEDUCATION IN THE CURE OF CARDIOVASCULAR DISEASE RESULTING FROM HIGH TENSION.

By LOUIS FAUGÈRES BISHOP, M.D.,
NEW YORK.

The recognition of the functional element in cardiovascular disease marks perhaps the greatest single advance in the appreciation of the therapeutic needs of patients suffering from disorders of the heart and circulation. If we believe that the therapeutic modification of function is of advantage only so long as the effect of our remedies lasts then must we indeed be therapeutic nihilists, for truly enough we cannot continue indefinitely to use vasodilators, cardiac stimulants, and alteratives. We have faith in the cure of cardiovascular disease because the persistent and patient modification of function by diet, drugs, suitable exercise, and a carefully selected environment finally educates the person's physiological activities so that they act normally after the withdrawal of active measures. This education or reeducation by which functional derangements are removed, holds out hope of a permanent cure of hypertonia vasorum and the removal of damaging high blood pressure. It is, of course, most useful before tissue damage has been wrought by the pressure violence to the nutritive vessels of the heart, brain, or kidneys.

In an early case of high arterial tension of nervous origin the important element in physiological reeducation consists in training the victim to eliminate worry and a tendency to too great concentration of interest in whatever pursuit is occupying him. Worry is in a measure a habit, and can be eliminated by a person of strong intellect, who definitely decides to let events in a measure take their own course, and the too great concentration of attention on one's occupation is a self-indulgence that often ignores the importance of other things and the legitimate claim of the lighter things of life upon the attention.

The business man should be contented with a reasonable financial success, and the professional man with a reasonable degree of distinction. The patient should deliberately eliminate under the advice of his physician all unnecessary burdens of responsibility. If the man or woman has occupied a position of trust, and has given that devotion to his work that has led to hypertonia in his circulation, he is certainly entitled to pass the burden on to some one else. Often enough when unnecessary burdens are thrown off it is perfectly possible to take care of what are left. The world is not going to be reformed in one generation, and no one was ever meant to carry the burdens of the universe.

Next to worry and undue concentration of mental effort comes the question of nutrition and diet. Many persons consider themselves undernourished, when in fact the opposite is the case.

A critical examination of the blood and urine often shows distinct evidence of an excess of food in persons, who are seeking to be built up by physical rest and a diet selected for its nutritious qualities. When this is the case, the food should be restricted in quantity—sweets eliminated, and meat greatly reduced in quantity. The popular prescription of withholding from these patients all food that has contained blood may be extreme, but it is in the right direction. Third, but not least in importance, is the matter of physical exercise. Here we come upon the relationship, which I have often traced, between the tone maintaining function of the brain over the voluntary muscles, and a possible similar function with regard to the involuntary muscles. Exercise should be carried on systematically, whether the patient feels like it or not. A distaste for physical exercise often goes with this condition, and must be overcome by emphatic instructions of those responsible for the welfare of the patient. There is undoubtedly some advantage in the resistance movements, though massage does not seem suited to many patients with high blood pressure. It has seemed to me that the resistance movements were valuable in removing overtone through some connection with the tonus of the voluntary muscle. While the patient is under treatment or reeducation the circulation must be regulated as far as possible by drugs that improve the muscular tone of the heart, and those that overcome an excess of tone in the blood-vessels. These must be given under skilled direction of some one who has the knowledge and authority to regulate the time, quantity, and nature of the medication, almost from hour to hour, to meet the manifestations of the pathological physiology of the disordered circulatory system. In some instances a few weeks will counteract the commencing high tension and the individual may go on for years without its developing again. In more severe cases several months are necessary. In those that have lasted a long time a year is necessary for the physiological reeducation. The intelligent cooperation of the patient and the friends of the patient are absolutely necessary. In difficult cases the work is most discouraging at first, though often enough after a few weeks the beneficial results become rather suddenly apparent to every one. Where there are distinct evidences of broken compensation, treatment must, of course, be commenced by keeping the patient in bed, but these very patients can often least afford the debilitating effect of bed treatment, and the sooner outdoor treatment can be instituted the better. An attack of apoplexy does not preclude the possibility of good results from physiological education in high pressure cases, but, of course, makes the problem more difficult. Particularly is this true when, as is often the case, there is a distinct tendency to depression of spirits, approaching melancholia; for the mental tension that goes with this state makes the high tension hard to control. Physiological reeducation should begin early, but unfortunately this newly recognized condition of idiopathic vascular overtone is not generally enough recognized for the necessity of such active treatment to be appreciated as often as it should.

In its early stages it is a disease without symptoms because the heart first brings into play its reserve force, and then painlessly becomes enlarged, and the severer accidents of the development of Bright's disease, of apoplexy, or heart failure only have to do with the fully developed condition. It behooves every one, particularly if over fifty, to have vital organs inspected at regular intervals, so that overtone may be early recognized and prevented.

In a paper read before the New York State Medical Society this winter in Albany the former president, Dr. H. L. Elsner of Syracuse, pointed out that physicians themselves should be on their guard lest they suffer from the evils of high tension in their own circulation.

New York, July 13, 1907.

HYGIENIC REQUIREMENTS IN BOOKS AND JOURNALS.

ONE would suppose that medical men, who preach hygiene at every convenient opportunity and who accept unhesitatingly, in theory, the principle that prevention is better than cure, would be themselves the first to apply the hygiene they advocate, even if they cannot force it as yet upon the world at large. Yet it is a curious fact that, in the aggregate, physicians are as little given to hygienic living as laymen of the same social grade. A little reflection, and perhaps a little introspection, will convince any one that there is no exaggeration in this statement. In view of this one finds no occasion for surprise that many of the books and some of the journals printed for the use of medical men offend against all the rules of ocular hygiene. The human eye was developed under conditions very different from those which now prevail in civilized life, and that its prevailing employment in reading, writing, and other near work is not that for which it was constructed, but strains it to and beyond the point of fatigue, is undeniable. The headaches and other ocular reflexes consequent upon the use of the uncorrected, and the abuse of even the corrected, eye carry conviction of the truth of this statement. It is too late, it is impossible, to return to Nature; civilized man's eye work is near work. In the course of ages, perhaps, the human eye will be able to read the finest print with ease, while the limits of distant vision will be drawn closer. Whether man's sum of happiness will be thereby increased or lessened depends upon the point of view. In the meantime it is the duty of printers and publishers to supply him with reading matter of such an exterior as will put the least possible additional strain upon his already much abused eyes.

In the *Popular Science Monthly* for June, 1907, Professor Edmund B. Huey discusses the hygienic requirements in the printing of books and papers. Just what form of type, spacing, and size of page are least offensive to the eye are matters which have not yet been definitely settled, but of some requirements, he says, we can now be certain, and these should be vigorously enforced in the printing of school books and government publications, and we may add of those intended for use by medical men. The optimum type is of the size called eleven point, and fatigue of the eye and brain increases rapidly as the size of type decreases. As a compromise between the printer and the reader ten point type—the type of this page—is satisfactory, but any below eight point—the smaller type of the Society Reports in the MEDICAL RECORD—is inadmissible. The space between the letters should be from 0.3 to 0.5 millimeter, and wide spacing, such as is used instead of italic in German publications and in a few unwise imitators among medical journals in this country, is confusing and trying to the eyes. The legibility of the smaller type is increased somewhat by leading, or the spacing between the lines, but it is questionable whether Javal is not right in holding that the space for such interlignage could more advantageously be used for larger type, with less leading. The length of line, Huey says, is very important. A long line necessitates considerable lateral movement of the eyes, and it also calls for more or less assymmetrical accommodation, since, except at the middle point, the reading matter is always further from one eye than the other. In reading a short line the excursions of the eye are about nil, since the beginning and end of each line are read in indirect vision. There is less fatigue therefore in reading a page divided into columns of the width of those in this journal than in reading lines of page width, such as are found in some of the medical journals of magazine form.

As regards books, those of smaller size, which can be held in the hand, are preferable to those of large size and great weight, since "the larger books usually have to lie on a support, which exposes the letters at an angle, greatly lessening their legibility and producing the equivalent of a material decrease in the size of type." Another important requirement, to which Mr. Huey refers, and one upon which we have repeatedly commented, is that the paper should be without gloss, which is especially trying to the eyes. Medical publishers are often great offenders in this respect. In order to bring out the halftone illustrations well they use highly sized paper, with the result that the eyes of the reader are dazzled and fatigued by the reflection of light from the polished surface. This is a great evil, and it is one found in some medical journals as well as books. However much the illustrations may add to the value of an article or a treatise, they should be subordinate to the text. The paper of the reading page should be white in color and dull in finish, and the already sufficiently strained eyes of the reader should not be made to suffer still more for the sake of a halftone or an *x*-ray picture.

Mr. Huey, in concluding his interesting article, quotes Shaw, who says in his "School Hygiene": "Principals, teachers, and school superintendents should possess a millimeter measure and a magnifying glass and should subject every book presented for their examination to a test to determine whether the size of the letters and the width of the leading are of such dimensions as will not prove injurious to the eyes of children. If every book, no matter what its merits, were rejected if its type were too small, the makers of such books would very quickly bring out new editions with a proper size of type." This recommendation applies with equal force to books and journals offered to the medical reading public, and it is worthy of consideration by the publishers of such works.

THE RUSSELL SAGE INSTITUTE OF PATHOLOGY.

In giving the sum of $300,000 for the purpose of endowing an institute for pathological research to be connected with the City Hospital and City Home on Blackwell's Island, Mrs. Sage has indicated a new field for benefaction by public-spirited citizens of wealth. The city's institutions on the Island have always suffered through lack of adequate facilities in this direction, and though of late years, thanks to the more enlightened spirit in which the office of Commissioner of Charities has been administered by its recent incumbents, conditions have greatly improved in many other ways, little or no provision has been made for the proper support of the pathological work. By the establishment of this fund the control of the laboratory is definitely removed from the sphere of political interference which would inevitably come into action were the attempt made to improve the existing conditions by placing the scientific workers on the pay rolls of the city. Through the cooperation in this way of private beneficence and municipal support, the extremely valuable material of the city's institutions can be satisfactorily studied by salaried investigators, special research work can be provided for, the necessary equipment and library facilities can be supplied, and the results obtained can be published in suitable form. The practicability of such a combination has already been demonstrated by the success of the Senkenburg Pathological Institute of the City Hospital of Frankfort, Germany, and on a somewhat smaller scale in Boston, where the City Hospital has at its disposition a number of private endowments. Under the administration of the wisely selected board to which Mrs. Sage has entrusted the management of the Institute, its value to the city and to medical science is assured, and New York is to be congratulated on a noteworthy addition to its list of scientific institutions.

The importance of this gift is far from being merely local, however. It has often been pointed out that though the average expectation of life has been lengthened during the last decades, it is only the younger individuals who profit by this practical result of the advances in medical knowledge enjoyed by the present generation. This is not strictly true, since it has been shown that length of life is increasing even for those past the half century mark; nevertheless it is mainly in dealing with the infectious diseases—which have their greatest mortality among the young and middle-aged—that preventive medicine asserts its triumphs, while the maladies and tissue changes of middle age and senescence have undergone no commensurate study. Leaving aside the question of cancer research, the study of the diseases of advanced age bulks small in the annals of modern investigation, and though many valid reasons can be urged in support of this discrimination, the time seems ripe for an extension of the field of effort. Mrs. Sage, and those whose counsel shaped her benefaction, have pointed a way which it is to be hoped many others will follow. In every large city there are public institutions rich in material demanding elaborate clinical and laboratory study at present out of the question through lack of financial support. By the establishment of funds similar to the Blackwell's Island foundation not only would the immediate lot of the inmates of such hospitals and homes be alleviated through the increased interest in their care, but results of the greatest possible importance to the race at large would be achieved in no small measure.

PARETIC DEMENTIA.

The diagnosis of paretic dementia is not always easy, as its symptomatology may be closely simulated by that of other forms of disease of the nervous system. Dependence should not be placed on any one symptom or even on a small group of symptoms, but careful consideration should be given to the aggregate of physical symptoms and signs. The disease has been defined as a parenchymatous degeneration due to a loss of durability of the nerve-cells and a premature decay of tissue in which inherited and acquired conditions take part, with the result that progressive death of the last and most highly developed nervous structures ensues as soon as their initial energy is unable to cope with the antagonistic influence of environment.

In a paper dealing with the clinical aspects of paretic dementia, Dr Irwin H. Neff (*American Journal of Insanity*, April, 1907) expresses the opinion that the disease has an organic basis, on which mental symptoms are superimposed. He holds that the clinical inconsistencies by which frequently the affection is marked and the association of analogous symptoms with other forms of organic disease render it improbable that paretic dementia represents a definite and exclusive mental entity. In other words the syndrome of paretic dementia may be brought about by various causes. Heredity of indirect character is probably a not infrequent predisposing factor. In view of the facts, the clinical differentiation is at times impossible. The late appearance of so-called characteristic mental and physical signs may prevent accurate diagnosis. The differentiation from arteriosclerosis of the nervous system, cerebral syphilis, chronic alcoholic insanity with organic changes in the brain, cerebral tumor, and sclerosis of the brain may be impossible, especially at an early or incipient stage. If paretic dementia be considered an organic disease of the brain, with secondary mental changes, its vagaries can be readily recognized and appreciated. A comparison of the mental symptoms with those of other forms of organic disease of the brain establishes clearly the absence of a well-defined clinical picture and the presence of multiform mental and physical signs.

Decapsulation of the Kidney.

Renal eclampsia and chronic Bright's disease have within the last few years been brought more or less within the domain of surgery. Felix Piéri of Marseilles has resorted to decapsulation several times in severe cases of eclampsia, and discusses in the *Annales de Gynécologie et d'Obstetrique*, May, 1907, the pathology, manner, value, technique, and indications of this operation, reporting several cases. He likens the kidney in eclampsia to the eye in glaucoma; increase in size, reddish-brown color, hypertrophy of the cortex, congestion, a diapedesis

of leucocytes, and alterations in Bowman's capsule are among the more common pathological findings. The operation consists of an incision the whole length of the external border of the kidney through the capsule, but not deep enough to destroy the parenchyma; then with the finger the capsule is torn down to the hilum both anteriorly and posteriorly. This is followed by a profuse hemorrhage, which relieves the congestion, frees the gland from its prison, and allows the exudates and toxin-laden blood to escape through the wound. The kidney is replaced and thorough drainage is established. The decapsulation is usually bilateral, especially if the toxemia is severe and rapid in onset. The hypertension being relieved, the secretory and circulatory functions of the kidney are immediately restored. The size is reduced, pressure on the glomeruli is lessened, and the mechanical, as well as the chemical, disturbances are removed. Eclamptic seizures cease, the amount of urine increases, and albumin rapidly diminishes. The author is not in accord with those who prefer conservative medical treatment at first, and favor a resort to surgery only after failure of the former, for in view of the pathology, he holds, surgical treatment is indicated as soon as the diagnosis is made. Its action is threefold; it arrests the process of nephritis, restores secretory functions, and stops the intoxication. Phocas and Bensis of Athens discuss the subject of decapsulation in the treatment of chronic Bright's disease in the issue of the *Archives Provinciales de Chirurgie* for April, 1907. Their operations were unilateral except in very severe cases, and even then there was an interval of nine or ten days between the interventions. Their operation differs but slightly from that of Piére in that a small incision only is made in the capsule before stripping by the finger. The results of the operation, the writers claim, are prompt and satisfactory. Dyspnea disappears, edema and ascites are rapidly diminished, and the lesser symptoms, such as headache, indigestion, vomiting, and diarrhea cease. There is a diminution in the quantity of the urine and a temporary increase of albumin. The latter, however, lasts but a day or two and then the amount gradually diminishes until at the end of a month or six weeks not even a trace is present.

Primary Typhlitis without Appendicitis.

It was formerly believed that all inflammatory diseases in the right iliac fossa originated in the cecum and were the results of a catarrhal process due to stagnating fecal masses (typhlitis stercoralis). The prevalent opinion now is that most of these conditions are in reality appendicitis. Deaver, Ochsner, König, Sonnenberg, and others deny the existence of a primary localized inflammation of the cecum without appendicitis. In the *Annals of Surgery* for June, 1907, C. A. McWilliams, treating of the subject of typhlitis without appendicitis, quotes many authorities both *pro* and *con*, and reviews the recorded cases of the past seven years. He admits that primary typhlitis is rare in comparison with appendicitis, but feels justified from the evidence which he has collected in holding that primary acute and chronic typhlitis may occur independently of appendicitis, dysentery, tuberculosis, actinomycosis, or cancer, and that it may be either idiopathic in origin or due to coprostasis. Numerous autopsy reports and findings at operation have confirmed him in this opinion. The disease in the cecum may go on to ulceration and perforation with the formation of a perityphlitic abscess or general peritonitis, while the appendix remains normal. Howard Kelly alone has reported fourteen cases presenting primary lesions in the cecum, the appendix being normal. The symptoms of typhlitis are similar to, and usually undistinguishable from those of appendicitis, and the indications for operation are also similar in the two conditions. It is well to bear in mind, however, that there is such a disease as primary typhlitis, especially when dealing with patients who have been operated upon for chronic appendicitis and who suffer from a recurrence of symptoms. This recurrence may be due to an attack of typhlitis, the treatment of which consists in the regulation of the diet, in the use of oil enemata, etc. Haberer reports that of ninety-six interval operations for appendicitis, in only fifty were the symptoms entirely relieved by the operation; forty patients continued to have more or less marked symptoms, such as obstinate constipation and severe pain, from which they had suffered prior to operation.

A Diagnostic Sign in Appendicitis.

While the study of the symptomatology of appendicitis has been developed to a very satisfactory degree, instances still occur in which the methods in common use do not meet all the requirements. Blumberg (*Münchener medizinische Wochenschrift*, June 11, 1907) describes a sign pointing to peritoneal irritation or inflammation which he considers will be found of assistance in the diagnosis of all peritoneal conditions, and especially of appendicitis. It consists in the fact that in palpating the abdomen in the neighborhood of an area of inflamed peritoneum, not only is the downward pressure painful, but if the examining hand is suddenly removed the abrupt recoil of the abdominal wall also gives rise to pain. The author has found that during an acute attack of appendicitis with peritoneal involvement patients invariably state that the pain caused by the sudden removal of the hand is greater than that caused by the pressure, while if the inflammatory process is subsiding the two painful sensations first become equal in intensity, and finally the pressure pain is greater than the other. The author believes that the sign is especially valuable in determining whether or not operation is indicated in early cases since its presence indicates that the peritoneum has already begun to take part in the inflammation. Its sudden appearance is therefore a danger signal, while its gradual diminution in intensity points to a subsidence of the peritoneal reaction. The advantage of the method is that it does not require an absolute estimation of the degree of pain caused by the palpation, which is often difficult to obtain, but demands simply a comparison of the intensity of the two painful stimuli which most patients are able to determine accurately.

Brass-Founders' Ague.

As in many occupations concerned with the smelting of metals, brass workers also suffer from various symptoms, which in this special instance are referable to the zinc used in making brass. These symptoms are tightness and oppression of the chest with indefinite nervous sensations, followed by shivering and profuse sweating. From a recent issue of the *Lancet* we learn that the English authorities have advised that certain regulations be put in force in connection with brass founding. Thus it is proposed that the pouring of brass should be prohibited unless there be (*a*) an efficient exhaust draught for the removal of the fumes at, or as near as possible to, the

point of origin, (*b*) efficient arrangements to prevent the fumes from entering any room or factory in which work is carried on, and (*c*) free openings to the outside air in the upper part of the room. Provisions are also laid down for the maintenance of a lavatory supplied with warm water, soap, nail brushes, etc. Women and girls are not allowed to work in any process whatever in which the pouring of brass is carried on. The most important of these regulations is the requirement of efficient means to remove the fumes which are the chief source of injury to the health of those engaged in the casting shops.

A Successful Campaign Against Criminal Abortion.

At the recent annual meeting of the Chicago Medical Society, Dr. Rudolph W. Holmes, Chairman of the committee, reported that the work had been principally in the direction of securing the removal of advertisements of abortionists from the daily press. In this the committee has been remarkably successful, having brought about a condition which never obtained before. It has removed all criminal medical advertising from the Chicago newspapers. Three of the leading newspapers consented to this line of action after a presentation of the facts by the committee. The others complied only after being notified by the postal authorities that they must comply or have their papers excluded from the mail, the committee having furnished the government with proof that the advertisers were willing to perform abortions. The committee also rendered valuable service in the prosecution of criminal operators, with the result that at least two have been sent to the Joliet penitentiary, others have left the city, some are being prosecuted, and the others and the newspapers are being watched. The work of this committee shows what can be accomplished by fearless, conscientious men, who are working for the good of the people.

News of the Week.

XIVth International Congress of Hygiene and Demography.—The detailed program of this congress, which is to be held in Berlin, September 23 to 29, 1907, has been issued and provides for an extensive series of discussions to be held under eight sections. The German steamship lines offer reduced rates to members attending the congress, and accommodations in Berlin may be secured through the Reise-bureau der Hamburg-Amerika Linie, Berlin W. 64, Unter den Linden 8. Tickets of membership may be obtained from the General Secretary, Dr. Nietner, Berlin 9, W. Eichhornstrasse 9. Full membership costs $5, and passive membership, which does not entitle the holder to take part in the discussions or to receive the printed report of the congress, costs $2.50.

Deaths Caused by the Fourth of July Celebration.—Reports received by the *Chicago Tribune* before midnight July 5 showed that the number of those dying as the direct result of the Fourth of July celebration was at least forty-five and the number of injured over 2,500. Since that time the figure has been greatly increased by later reports, and the number of deaths also will no doubt prove to be much greater. The statistics show a very considerable increase in the number of casualties and the amount of fire loss as compared with last year. In New York City three were killed by pistols and 126 were more or less seriously wounded by the same weapons. The number of those injured in this city by firecrackers and other explosives was over two hundred.

A New Street Cleaning Commissioner.—Mr. Macdonough Craven, Commissioner of Street Cleaning of New York City, has resigned, and the Mayor has appointed Dr. Walter Bensel in his place. Dr. Bensel is a graduate of the College of Physicians and Surgeons in the class of 1890, and has for fifteen years been connected with the Sanitary Bureau of the Department of Health, where he has done efficient service.

An Application for Additional Milk Inspectors.—Mr. Charles S. Hervey, Supervising Statistician and Examiner of the Department of Finance, has presented to Comptroller Metz a report on the application of Health Commissioner Darlington for $175,000, to be appropriated by the Board of Estimate for the purpose of hiring 100 additional inspectors to aid in the examination of the milk farms that supply the city. In his report Mr. Hervey quotes at length from the reports made in connection with the recent Aldermanic investigation of the pure milk question, and also from the report of the Mayor's special commission. He also relates the efforts of the Health Department, with its comparatively few inspectors, to accomplish results worthy of mention, and presents an exhaustive compilation of the analysis of samples of milk, together with figures showing that 119,163 inspections were made in 1906, 41,395 quarts of bad milk were destroyed, 660 arrests were made, and $12,880 was collected in fines. In conclusion, the examiner raises the question whether or not, with the additional force of 100 inspectors, the 30,000 or 40,000 farms, dairies, and creameries in the six States which supply milk to this city could be so effectively inspected as to insure the milk supply being pure.

Rockefeller Institute Appointments.—The Rockefeller Institute for Medical Research has adopted the following series of titles for its staff: Member, Associate Member, Associate, Assistant, Fellow, and Scholar of the Rockefeller Institute, and has made the following list of appointments: Members: Simon Flexner, Director of the Laboratories, pathology; S. J. Meltzer, physiology and pharmacology; E. L. Opie, pathology; P. A. Levene, biological chemistry. The following have been appointed as Assistants: Hideyo Noguchi, John Auer, Alexis Carrel, J. W. Jobling, Nellie E. Goldthwaite. The following are Fellows: C. M. A. Stine, Donald Van Slyke, Martha Wollstein, Maud L. Menten, Mabel P. Fitzgerald, Don R. Joseph, Benjamin T. Terry, Thomas W. Clarke. Scholar, Bertha I. Barker. Grants to aid special researches have been made to twenty non-resident workers.

St. John's Guild Floating Hospital.—The hospital steamship of St. John's Guild began its regular trips on Monday. The landings are West Fiftieth, West Thirty-fifth, and West Tenth streets on Mondays and Wednesdays, East Twenty-fourth, East Third, and Market streets on Thursdays and Saturdays, Metropolitan, Hudson, and Hamilton avenues, Brooklyn, on Tuesdays and Fridays. The vessel runs down to New Dorp, S. I., and return. The Seaside Hospital of the Guild is at New Dorp. Tickets of admission have been issued to the Department of Health, hospitals, and dispensaries, and any practising physician may obtain them on application at 501 Fifth avenue.

Jewish Maternity Hospital.—Plans have been filed for enlarging and remodeling the two four-

story and basement buildings at 270 and 272 East Broadway for the newly established Jewish Maternity Hospital. The remodeled edifice is to have a roof garden, and the necessary improvements are to cost $15,000.

Coroner's Records for June.—The Coroner's office during June received reports of 498 deaths. Of this number 236 were due to violence or accident, the remaining 262 being sudden deaths due to natural causes. Of the deaths by violence or accident, 52 were homicides, 29 were suicides, 39 bodies were found floating in the river; 80 persons were killed by fractures received from falls, 7 were killed by the collapse of a building, 14 died of gas poisoning, drug poisoning killed 7, two were shot, 4 were burned to death, and 2 resulted from caisson disease. Sixteen persons were killed by vehicles, 15 by the street railways, 9 by assault, 3 by malpractice, 3 by automobiles, and 3 by shooting. Of the suicides, 7 persons drowned themselves, 6 died by shooting, 4 by jumping, 6 by gas, 4 by throat cutting, and 2 by poison.

The New York Polyclinic for Diseases of the Stomach opened Saturday, July 6, at 521 East 120th street, the site of the old Harlem Hospital, under the direction of Dr. Mark I. Knapp. Part of the building will be reserved for original research, and as soon as practicable courses of instruction will be given in diseases of the gastrointestinal canal.

Illinois Branch of the Public Health Defence League.—This league is beginning an active campaign in Illinois. It is hoped that by October a State branch of the League, with headquarters in Chicago, will be thoroughly organized and equipped to carry on this vitally important work of assisting the constituted authorities in conserving the public health. The objects of this League are (1) to combat all forms of quackery and charlatanism; (2) to prevent food adulteration and drug substitutions; (3) to prevent the sale of narcotics and alcohol, disguised as patent medicines; (4) to prevent the circulation of indecent medical advertisements; (5) to advocate the establishment of a national department of health; (6) to carry on an educational campaign for the spreading of active knowledge concerning the public health and the inculcating of higher ideals; (7) to protect the public health by assisting its constituted authorities in the enforcement of existing laws, and by urging the enactment of uniform legislation in all the States on matters relating thereto; (8) to cooperate with other societies interested in any public health problem, and ultimately to effect a plan of union or cooperation of all organizations interested in the public health.

Hydrophobia in Chicago.—The bacteriological laboratory of the Chicago Health Department has improved its technique in the examination of material from animals suspected of rabies, so that the diagnosis can now be made within about an hour. The value of the method is attested by the satisfactory results that have attended its use in the New York Board of Health Laboratories since its introduction some time ago.

Dr. Walter F. Parker, Professor of Ophthalmology in the University of Michigan, has resigned and will devote himself to private practice in Detroit. His successor has not yet been selected. The chair is a full professorship, including ophthalmology only.

Dr. Abr. L. Wolbarst has been elected Professor of Genitourinary Diseases in the New York School of Clinical Medicine.

Typhoid Fever in Pittsburg.—The epidemic of typhoid fever in Pittsburg is increasing rather than diminishing in severity, and 498 new cases were reported during the month of June.

Probability of Death from Cancer.—Sir William Church, ex-president of the Royal College of Physicians, in addressing the Committee of Imperial Cancer Research Fund on July 1, said that the probability of dying from cancer was now one in twelve for all men above thirty-five years, and one in eight for all women above that age, as contrasted with one in twenty-one and one in twelve twenty years ago.

An Epidemic of Ptomain Poisoning.—About fifty persons living in Stamford, Conn., were made seriously ill on July 4 as the result of eating ice cream supposed to have been made from improper materials.

An Alleged Inexpensive Radioactive Substance.—The newspapers have been printing numerous cable despatches describing a new radioactive substance possessing many of the properties of radium bromide, and capable of being produced very cheaply. This was said to have been discovered by a young medical student, but unfortunately later reports state that the new body has little or no practical value as a source of radioactivity.

Boys Arrested for Selling Cocaine.—Four boys between the ages of fourteen and seventeen years were arrested last week in Newark for selling cocaine to schoolboys and were held for action by the Grand Jury. The youngest of the four was already under probation on a similar charge.

Japanese Immigrants Turned Back from Mexico.—A shipload of Japanese laborers who were brought direct from Japan to the port of Salina Cruz, Mexico, under contract to work in the mines, are being held in quarantine on account of the presence of disease among them, and will probably be turned back by the health authorities.

New Jersey State Medical Society.—At the meeting of this society held in Long Branch on June 26 officers were elected as follows: *President,* Dr. Edward J. Ill of Newark; *Vice-Presidents,* Dr. David St. John of Hackensack, Dr. B. A. Waddington of Salem, and Dr. W. J. McKenzie of Trenton; *Recording Secretary,* Dr. W. J. Chandler of South Orange; *Corresponding Secretary,* Dr. Daniel Strock of Camden; *Treasurer,* Dr. Archibald Mercer of Newark. The next meeting will be held in Cape May.

An English School for Mothers.—What is known as the St. Pancras School for Mothers has been opened in London. About fifty mothers are said to be already attending the school, which gives instruction in the care of children and provides a dinner for each pupil.

Obituary Notes.—Dr. Alfred W. Ford of Brooklyn died on July 2 of apoplexy. He was born in Augusta, Me., in 1853, and after graduating from the University of Virginia he received his medical degree from the New York University Medical School in 1872. He began practice in Brooklyn, and was made a member of the Board of Police Surgeons in 1886. He had long been a surgeon of the Sixty-ninth Regiment.

Dr. Richard H. Derby of this city died in Litchfield, Conn., on July 4. Dr. Derby was born in Boston in 1844, and was graduated from Harvard at the age of twenty years. Three years later he received his medical degree from the Harvard Medical School, and in 1870 he began practice in this city.

He early specialized in ophthalmology, and became connected with the New York Eye and Ear Infirmary in 1874. At the time of his death he was surgeon to this hospital, a member of the State Charities Aid Association, and a trustee for the New York Institution for the Blind.

Dr. JOHN MONSELL PEACOCKE of Brooklyn died suddenly on July 3, at the age of fifty-nine years. He was born in Limerick, Ireland, and was a druggist in Glasgow before coming to this country. He was graduated from the College of Physicians and Surgeons of this city in 1883, and had practised for many years in Brooklyn.

Dr. ALBERT E. CARRIER of Detroit died suddenly of heart disease on July 4 at the age of sixty-six years. He was well known as a specialist and as a dermatologist.

Dr. WILLIAM H. NELSON of Taberg, N. Y., died last week at the age of seventy-seven years. He had practised for nearly fifty years in Taberg, and was well known throughout the central and northern parts of the State.

Dr. DAVID GRANT of Los Angeles, Cal., died in Inverness, Scotland, on June 3, at the age of fifty-six years. He had spent many years in China as a medical missionary, and in Los Angeles, as an ophthalmologist, had made a specialty of diseases of the eye.

Dr. S. J. M. COX of Johnston, S. C., died on June 26, at the age of sixty-one years, after a long illness. He was born in Burke County, Ga., and had practised in Johnston for twenty-eight years.

Dr. CHARLES MUNGER of Knoxboro, N. Y., died on June 19 of cerebral hemorrhage. He was born in 1841, and was graduated from Bellevue College in 1871, having received part of his medical training at Ann Arbor. He practised in Knoxboro from 1871 to the time of his death.

Dr. EDWARD J. HADFIELD died at Phenixville, Pa., on July 6, at the age of thirty-nine years. He was graduated from Jefferson Medical College in the class of 1890.

Dr. R. E. WORLEY, a medical missionary to China, died at Swatow on July 7. He was a graduate of Rush Medical College, Chicago.

Dr. CHARLES W. CUNNION of Brooklyn died on July 7, in his thirty-fourth year. He was a graduate of the Manhattan College and the Long Island College Hospital.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

AMALGAMATION COMPLETED—ROYAL SOCIETY OF MEDICINE—COLITIS—FOOD EXPERIMENTS ON FOWLS—INTERNATIONAL CONFERENCE ON SLEEPING SICKNESS—PLAGUE—NOTIFICATION OF MENINGITIS—MEDICAL BILLS IN PARLIAMENT—OBITUARY.

LONDON, June 21, 1907.

THE amalgamation of our societies is now complete and in future we have the Royal Society of Medicine, with sections which embrace the societies which are thus replaced. A sort of continuity will thus be retained in the union of the several organizations. The first president of the new Royal is Sir William Church, and a strong council has been appointed, as well as honorary officials.

At the special meeting of the Medico-Chirurgical on the 14th the supplemental charter was "dutifully accepted" and adopted and thus the title Royal conferred on the new organization. The by-laws submitted by the committee of representatives of the several uniting societies were adopted as those of the Royal Society of Medicine. The president stated that much detail had yet to be accomplished and the new society would not be in full working order until the autumn.

At the concluding ordinary meeting of the Medico-Chirurgical before absorbing its sister societies Mr. Lockhart Mummery read a paper on colitis based on thirty-six cases. The sigmoidoscope had proved of great value in the study of the disease by bringing to light definite lesions in the lower bowel, mostly of a chronic nature. Ulceration was demonstrated in seven of the cases. The ulcers were irregular in outline and size, shallow, involving only the superficial layer of the membrane. In six cases Mr. Mummery found a new growth which had not been indicated by the symptoms. Among causes he mentioned pericolitis, abscess, chronic appendicitis, adhesions binding down and constricting the colon. The separation of these adhesions mostly sufficed to cure such cases. A much rarer cause was multiple adenomata of the colon. Abdominal aneurysm had seemed to be one cause. In only six of the cases had he failed to discover an adequate local lesion and he held that such a cause should always be searched for and must almost always be found.

Dr. Hale White said membranous colitis was a definite disease. The cases submitted in the paper were a small group which he distinguished as mucomembranous, in which the value of the sigmoidoscope could not be exaggerated. But there were other cases, especially in women, where no local lesion could be detected, and in these the whole colon might be affected.

Sir Dyce Duckworth said cases associated with nerve ailments were probably due to catarrh and many got well under treatment. There were all degrees of intensity and in some cases surgical aid might be needed.

Dr. Weber commented on the minor cases, which he, too, called catarrhal. Many might be due to chronic biliousness and were at first benefited by a dose of calomel. In other cases there were influenzal symptoms.

Dr. Cammidge found blood in the stools in five cases of cancer of the colon which he had examined, and regarded its constant presence as strongly suggestive. In forty cases of colitis he found the stools alkaline. The saponified fat was much in excess.

Dr. Phillips objected to attributing ulceration to constipation, which he thought was rather an effect than the cause. Some cases were syphilitic.

Dr. H. A. Coley considered some of the alleged causes were more likely consequences. Adhesions were probably the effect of pericolitis and appendicitis was more often the sequel of colitis than its cause.

A further paper was communicated by Dr. Forsyth, based on the results of feeding fowls on an exclusively meat diet and with a sufficient supply of lime. The experiment led to the conclusion that bone changes reported by previous observers were not caused by excess of proteids, but by insufficiency of lime. So with regard to the thyroid, the weight of one lobe alone had misled some, as the two were often unequal. Moreover, birds sometimes suffered from goiter.

On sleeping sickness an international conference is being held this week in London. To the invitation of this Government those which have colonies and protectorates in the infected regions have responded by sending delegates. The conference was formally opened by the president, Lord Fitzmaurice, in a speech enumerating the results of investigations already made, pointing out that cooperation would prevent overlapping of expert research and saying it is in the hope of organizing the forces of administration to the best advantage against the common enemy that His Majesty's Government has invited the powers concerned to send representatives. By way of initiating discussion he submitted for the consideration of the delegates the following, not as complete or excluding others, but to serve as a scheme for their deliberations: The question of holding annual or biennial conferences and of establishing a central bureau to circulate new literature on the subject. Further, as to the question of assigning definite points for investigation to particular countries or individuals, such as for example:

(a) Whether *Glossina palpalis* is the direct or indirect conveyer of the trypanosome. (b) Whether this undergoes developmental changes in the glossina. (c) If so, whether it is conveyed by the original glossina or by its larva when it reaches the virago stage. (d) How long an infected glossina continues infective. (e) Whether other species convey the trypanosome. (f) The distribution of the infecting species and their habits. (g) The rôle which vertebrate fauna other than man may play in spreading the infection. (h) The best methods for exterminating the glossina. (i) The best methods of preventing the introduction of the infection into virgin country, and (j) of controlling the spread of the disease in an infected district, including segregation of the infected and removal of those not yet infected. (k) The experimental study on animals of drugs which destroy the trypanosome. (l) The therapeutical application of these drugs to man.

The Croonian lectures at the College of Physicians this

year are being given by Dr. W. J. R. Simpson, who has taken for his subject "Plague." His opening lecture on Tuesday he devoted mainly to a description of the bacillus and its culture and an account of salient facts as to the history of the disease. This history is divided into two periods by the discovery of the bacillus in 1894—the first period extending over thousands of years, the second, so far, over only thirteen. The discovery gave certainty of diagnosis and led to the further discovery of Haffkine's prophylactic. The lecturer said that great epidemics not only destroyed large numbers, but left evil effects on the living, of whom many became overwrought, hysterical, fearful and selfish, so that the most sordid passions were displayed by the unbalanced portion of the population. As an instance he mentioned the massacre of the Jews in the great plague of the fourteenth century on account of rumors that they had poisoned the wells. A recrudescence of such suspicions had been seen in the Punjaub, where the British residents were regarded with suspicion. Various suggestions had been advanced as to the causes of the retrocession of the plague from Western Europe. One of them he certainly believed had considerable influence, viz., the change from overland to sea travel, with its consequent freedom from contact with trade caravans from the endemic centers in Messopotamia and Arabia. The lecturer then dealt with the dissemination by dogs, rats, and other animals. The association between rats and plague, he remarked, was a very old observation. On old coins Apollo and Æsculapius were each represented with rats at their feet.

Since the notification of "cerebrospinal fever" was made compulsory (March 12) fifty-six cases have been notified and the question has been raised whether the term includes posterior basal meningitis. The health committee of the County Council consulted the president of the Royal College of Physicians, who referred it to a committee, which has reported that there are cases in which differentiation is impracticable and added that so far as has been ascertained both diseases tend to occur during the earlier months of the year, and that although the occurrence of the disease in both instances is epidemic, in neither has it the characteristics of a spreading malady. It is therefore recommended that as the season of prevalence will not recur for seven to nine months the order for notification should he extended for two years, so as to cover two possible epidemic periods.

The Apothecaries' Bill has passed both houses of Parliament and only awaits the royal assent. It gives power to restore (with the consent of the General Medical Council) the name of a licentiate which has been removed, and it grants the desire of the licentiates to alter their title from L. S. A. to licentiate in medicine and surgery. Much good may it do them.

The bill for incorporating the King Edward VII. Hospital Fund is being delayed by a motion which has been introduced with a view to establish a council representative of medical and vested interests.

The bill for providing medical inspection of school children has passed the third stage and, unless the government push forward the larger measure, is likely to reach the statute book.

Dr. Julius Dreschfeld, Professor of Medicine in the Manchester University, died on the 13th inst., aged sixty-one. He was elected on the staff of the Royal Infirmary in 1873 and the next year to the Professorship of Pathology, Owens College. About a year ago he had to give up much of his work from ill health, and finally he succumbed rather suddenly. He was a physician of great attainments and had enjoyed a large consulting practice. He was elected a Fellow of the Royal College of Physicians in 1883, delivered the Bradshaw lecture in 1886 on "Diabetic Coma," and was to have given the Lumleian lectures next year. He was examiner from 1896 to 1898. He also served as examiner at the University of Cambridge and was an ex-president of the Therapeutical Society. His contributions to the medical sciences were numerous. As a teacher he was greatly esteemed.

The death is announced of Brigade Surgeon Benjamin Lane, who was born in 1827, entered the army as assistant surgeon in 1852, and retired in 1882. He was in the Burmese war, 1852-3, including the attack on Tomboo, received the medal and clasp, was mentioned in general orders by the Commander-in-Chief in India for his assiduous attention to the sick on the occasion when the whole detachment at Tomboo was suffering from fever. He was also mentioned in dispatches during the Indian mutiny and was on the banks of the Jumna in the action March 5, 1858, for which he was also awarded a medal. He leaves a son, who is one of the surgeons to Guy's Hospital, and three daughters.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

GONGOSA—THE CENSUS OF MANILA—LOW DEATH RATE AND IMPROVING HEALTH CONDITIONS.

MANILA, P. I., June 1, 1907.

THE regular monthly meeting of the Manila Medical Society was held at the St. Paul's Hospital at 8:30 P.M., May 6. Doctors Musgrave and Marshall of the Bureau of Science gave some further informal notes upon the case of gongosa which recently died at the St. Paul's Hospital, and mention of which has already been made. After reviewing the anatomical findings, Dr. Marshall expressed the opinion that no positive diagnosis could be made, but that it seemed to him that the lesions had many points in common with tuberculosis. A number of others who took part in the discussion pointed out, however, that if gongosa was a tuberculous manifestation it would seem remarkable that cases should be encountered only on the island of Guam and a few other Pacific islands, while tuberculosis is widespread throughout the world.

The census which the Bureau of Health took of the city of Manila during the month of January has finally been completed and will be used in compiling the vital statistics hereafter. It shows that the population of the city has grown from 219,941, the official figures of the United States census of 1903, to 223,542, which is an increase of 3,601, or 16.37 per 1,000.

The nationalities in which there was an increase are as follows:

American	810, or 18%
Filipinos	5,510, or 2%
Spaniards	375, or 14%
All other nationalities	248, or 27%

There is a considerable decrease in the Chinese population, the number having dropped from 21,230 to 18,028, or 15 per cent. The Bureau of Health accounts for the decrease in the Chinese population by: (1) The large emigration to the provinces which has taken place among the people of that nationality, as the peace conditions in the outlying districts have become more and more secure. (2) The operation of the Chinese exclusion law, which prevents the immigration of Chinese to the Philippines, thus preventing the replacing of the losses due to the mortality. (3) Few Chinamen have wives in the Philippines, consequently the birth rate is not sufficient to replace the number of deaths. (4) The return of many to China to spend the remainder of their lives. (5) The census being taken at a time when many Chinamen were visiting their country in order to celebrate the Chinese New Year.

The population of Manila by nationalities is now as follows:

Americans	5,199
Filipinos	195,202
Spaniards	2,903
Other Europeans	977
Chinese	18,028
All others	1,143
Total	223,542

The increase among the Americans probably caused more surprise than any other feature of the census, because it was the general impression that the American colony was steadily declining. The figures given above do not include the military.

Based on the above new figures, the death rate for the city of Manila for the first quarter of 1907 is 28.48 per 1,000, which is particularly low for a tropical country. This rate is apparently reached by many other tropical cities, but it is questionable whether the statistics are kept in accordance with the strict rules that are followed in Manila. Here all deaths due to violence and many cases that are usually classed as premature births are included. There are also hundreds of deaths occurring annually in the city among persons who come in from the provinces in order that they may die among their friends or to seek medical aid, or in order to be buried in some of Manila's attractive cemeteries. It is believed that if the statistics in other tronical cities were recorded on the same basis as those of Manila that this city would make a better showing than any other city of its size in the tropics.

During the month of April the weekly average of deaths for the city of Manila was 76.1, which is the lowest showing for any week since the American occupation. The next lowest showing was for the month of April, 1905, which was 78.9. This indicates that the health work which has been carried on systematically since the American occupation is gradually producing permanent results, and

the time is confidently looked forward to when the Philippines will be made as healthy as more temperate countries.

THE SCIENTIFIC TEMPERANCE FEDERATION.

To the Editor of the Medical Record:

Sir:—Within a very brief period the literature concerning the alcoholic problem has grown to enormous extent, and every year books, papers, studies of every kind and description are appearing until it is simply impossible for any student to follow everything written on this subject. To meet this want a society was organized last September in Boston, Mass., and incorporated by the laws of the State, called the Scientific Temperance Federation. Its object is to bring together all the facts and literature on this subject and make them available to every person who would like to know what is being said and done. This society is practically a bureau where every pamphlet, paper, and book containing information on any phase of the alcohol question can be gathered and put on file and made available for the student or specialist. The following quotation from its prospectus indicates the field that it will occupy: "Its aim is to bring together the facts developed by scientific research and experience, making them accessible to all persons interested in the great questions which grow out of this subject. . . ." It will enable the specialist, the student, and writer to place his conclusions on file where they can be sought for and examined and by this means all possible information on every phase of the subject concerning alcohol and narcotics can be brought together and made available. All books, pamphlets, papers, and statistical studies are classified and filed in such a way that the secretary can furnish an abstract on everything that is written, and in this way all writers of every description who wish to know the printed facts and studies of others can have them at their command. This society begins with a nucleus of over 2,000 pamphlets, books, and clippings gathered by the late Mrs. M. H. Hunt of Boston, Mass. This Federation will not conflict in any way with any other organization, but will endeavor to unify and supplement them by concentrating their work and making it available. For this purpose it is legally incorporated and expects to receive endowments and become a bureau of the greatest value for the dissemination of facts that are now lost for the want of such an agency. The subjects of alcohol and narcotics are closely related to insanity, crime, race degeneration, and the great problems of poverty, so that of necessity facts along these lines will be gathered and filed for study. For this purpose the bureau solicits papers, books, pamphlets, and data of every kind and description which can be classified and put in some available form for practical use. The Federation is a society with a small entrance fee, which entitles every member to an abstract or summary of all the facts on the literature of any particular subject along these lines. To others, not members, a small fee will be charged for a synopsis of any particular subject. A trained secretary will give her entire time and attention to the gathering and dissemination of facts bearing on these subjects. As chairman of the board of directors of this association I urge all writers and teachers who have anything new on these subjects to send them to this bureau, where they can be put on file and made available. The secretary, Miss C. F. Stoddard of 23 Trull street, Boston, Mass., will answer all inquiries for information.

The Radical Mastoid Operation.—W. S. Bryant discusses in particular the indications for and results from the employment of the radical mastoid operation. His general conclusions are thus summarized: (1) The radical mastoid operation assures cessation of the purulent otitis. (2) It is an operation for the immediate relief of this condition. (3) It may be the operation of final recourse. (4) The hearing is much improved after the operation, since in a number of cases the auditory function of the middle ear can be almost completely restored. A very small number of cases derive no improvement in their hearing from the operation. (5) The cosmetic results are very satisfactory. (6) Paralysis of the facial nerve is a very rare and unexpected accident in skilful hands. (7) The results are uniformly satisfactory when the best technique is employed.

Diagnosis and Treatment of Gastric Neuroses.—J. D. Dunham directs attention to some of the more common gastric neuroses. (1) Nervous anorexia or a complete absence of the sensation of hunger associated with loss of appetite usually follows some great mental depression. The patient must be appealed to for aid and shown that his co operation and will power are necessary to a cure. Food should be given frequently and varied. A bitter tonic should precede. The worst cases call for sanatorium treatment. (2) Nervous vomiting. Cause is often difficult to determine; may concern only certain articles of diet. The majority of cases show normal acidity and normal fermenting power. Mental depression is sometimes present. (3) Nervous dyspepsia presents no demonstrable change in the stomach. It may follow debilitating diseases. Sexual excess or abdominal genitourinary disease is more common in the male sex. The patient afflicted with this malady experiences discomfort after food, a sensation of fulness, slight burning, belching, drowsiness, fulness in the forehead. These symptoms often continue through the period of digestion, and are followed by sensations of dizziness or weakness. In many cases the patient will be uncomfortable at all times, whether the stomach is empty or full. The intestines are not free from apparent disturbance. The patient says he feels that his abdomen is filled with gas and he is usually constipated. The ideal method of treatment includes sanatorium care, cold baths, forced feeding, tonics, etc. The intragastric use of electricity seems to be of some service in allaying the hypersensitiveness of the gastric nerves, though this may be only suggestive. Too much attention should not be concentrated on the stomach in such cases, but the general neurasthenic condition treated in its entirety.

Gastrointestinal Disturbances in Influenza.—In the experience of J. Kaufmann the gastrointestinal tract is but slightly affected in grippe. We may have anorexia alone, constipation, or initial vomiting. Occasionally the alimentary disturbance dominates the clinical picture. Such cases often present lower temperatures than the respiratory grippe cases and are apt to be more protracted. We may find here nearly all the manifold symptoms of acute diseases of the gastrointestinal canal, including hemorrhages from the gums, pharynx, or rectum. The symptom complex of appendicitis is occasionally present. Influenza bacilli have been removed from the diseased appendix. Peritonitis may occur, serofibrinous, or purulent. But few cases of jaundice from grippe are on record. In addition to these inflammatory disturbances we have the group of symptoms referable to the toxins of the disease. Their paralyzing effect on the glands and nervous system of the tract often cause a very slow recovery. In some cases a loss of taste is a very annoying symptom. Sometimes the emaciation is so great and efforts to combat it seem so futile that a suspicion of malignancy is aroused.

Acute Edematous Eversion of the Ventricle of Morgagni.—A general description of the condition is given by T. J. Reardon, who reports one case—that of a woman singer, aged forty years, who presented at first the usual symptoms of a lacunar tonsillitis. In a few days she recovered, but after singing noted a huskiness of the voice. After a sudden exertion there quickly came on dyspnea cyanosis and marked stridulous breathing. Edema of the larynx was suspected. The author was then called in and the right ventricle of the larynx was found so edematous as to shut off a view of the cords. The mass was as large as a pigeon's egg. Right arytenoid was practically immobile on phonation and inspiration. Posteriorly there was a small triangular space for the passage of air. Intubation gave immediate relief and the next day the larynx was practically normal. The peculiar localization of the edema is due to the close attachments of the ventricular connective tissue to the thyroid cartilage and the internal and external thyroideus muscle.

Journal of the American Medical Association, July 6, 1907.

The Return to Transparency of Incipient Cataract.—L. Connor reports six cases of striated incipient cataract, in which five lenses became quite transparent, one lense lost seven striæ, one lens lost two striæ, one lens retained a trace of striæ, in two lenses the striæ had diminished two-thirds, one lens became lightly opaque, and one more opaque. In one diabetic case both lenses became transparent and remained so until the death of the patient. In all, the lens opacity was in its beginning stage and therefore more hopeful, but these results were unusual, and Connor therefore sent out letters of inquiry as to this point to a number of ophthalmologists, attention being directed to the presence of striæ in the opacity. To this were received fifty-five negative answers; fifty-seven negative with comments, and thirty-four affirmative replies. In all, including his own cases here reported, and the cases he could find reported in the literature, fifty-one observers report about 147 cases in which the opacity of incipient

cataract has regained transparency in whole or in part. After eliminating all indefinite answers enough remains to show that "opaque striæ, with or without adjacent lens opacity, have been seen to fade into clear lens substance." All agree that it is rare and that it is most frequent at the earliest stage of development. The question remains: How was it done? and a closer study of the early development of cataract is suggested.

The Role of the Wood-Tick in Rocky Mountain Spotted Fever.—Experiments which, in his opinion, unmistakably connect the wood-tick (*Dermacentor occidentalis*) with the occurrence of spotted or tick fever of man in the Bitter Root Valley, Mont., are reported by H. T. Ricketts. Guinea-pigs were the animals used and the technique is described. The experiments seem to show that the transmission is not a mechanical one, but that the insect is itself infected. One tick carried its infectivity for fifty-four days, whereas, outside the living body, the viability of the virus under the most favorable conditions is less than half this period. Drying the virus usually destroys it in two days or less, and under ordinary atmospheric conditions it lasts only a week, and it is difficult to suppose its life could be extended in the tick's mouth for fifty-four days. The infected dose of the blood of animals suffering from spotted fever has never been found by Ricketts to be less than 0.05 c.c., and usually the minimal pathogenic dose is nearer 0.1 c.c. Yet one small tick infected three guinea-pigs at successive intervals, which, allowing the blood to possess the highest virulence, would require, if the transmission was simply mechanical, a considerably greater volume than the bulk of the tick itself. Hence, it seems necessary to conclude that the virus proliferates in the tick. The experiments also indicate that the adult tick which infects man in the spring does not of necessity acquire its own infection in the spring, but may have acquired it from some possible source during the winter or autumn while in the nymphal stage. The possibilities of larval infection and of hereditary transmission are now being investigated and the results will be reported at some future time. That the local effects of the tick bite (erythema, edema, etc.) have no relation to spotted fever is clear, since they follow the bite of the uninfected tick, but that the virus of spotted fever is introduced with the saliva is the most plausible assumption, though the possibility of infection by regurgitation from the alimentary tract remains to be considered. The proof that the tick winters as a parasite on animals is conclusive, though exceptionally it may be found in other situations. Examples of exceptional development are occasionally seen and may account for the occasional cases of tick fever observed as late as August or as early as February, instead of in spring, the usual time. The distribution and dissemination of the ticks is discussed, as well as the susceptibility of other animals than man, which is being investigated. It is certain that the ticks have increased greatly in numbers since the Bitter Root Valley has been well settled and the quantity of stock has increased. The indigenous gopher or ground squirrel is susceptible to the infection, but less so than the guinea-pig, and one infection causes future immunity. Ricketts does not now maintain that this animal is exclusively responsible for the maintenance of the disease, though this is possible.

Blood Pressure Variations in Diabetes.—A. R. Elliott publishes the results of blood pressure observations in 25 cases of diabetes, 13 males and 12 females, 13 of them under 50 and 12 of them over that age. The average blood pressure of the former was 107 mm., and of the latter 150 mm. Their average weight was 138 for those under 50 years and 175 for those over that age. Age and weight are thus apparently of importance in determining the degree of blood pressure. Acid intoxication (diceturia) was observed in 9 of the 13 cases under 50, and in only one of the others. The degree of glycosuria had no apparent effect on the blood pressure; in 15 of the 20 there was a maximum glycosuria of over three per cent., and the average blood pressure in these was 121 mm. In the other 10 cases it averaged 135 mm. So far as a conclusion can be drawn from these cases, it is that an inverse ratio exists between the degree of glycosuria and the blood pressure. This might be looked for, as the milder cases of diabetes are apt to be in elderly persons with some arteriosclerosis and consequent high pressure. As regards acid intoxication, it would seem, from Elliott's 10 cases, to be attended with hypotension, and he is inclined to credit this to the generally more asthenic conditions in these patients rather than to acid toxins acting directly. In no case was the excessive hypertension declared by Potain and Teissier to be characteristic of diabetes observed. All the evidence points to the fact that it is to the complications, especially arteriosclerosis and chronic nephritis, that we must look for the cause of the cardiovascular secondary conditions. The cardiac hypertrophy noticed by pathologists is due to these causes and not to the diabetes. The observations confirm Janeway's statement that the disease of itself is without influence on arterial tension.

Latent Diphtheria.—M. Solis-Cohen criticises modern methods of handling diphtheria infection, which by the disinfection of comparatively harmless fomites, etc., create a false sense of security, while paying little or no attention to the virulent bacilli often carried about by those who have been in contact with the patients or by the convalescent patients themselves. He uses the term "latent diphtheria" for those cases without pseudomembrane, but due to the specific diphtheria organisms. Twenty-seven cases are reported briefly, in nearly all of which presumed diphtheria germs were demonstrated, mostly by culture method. Mild atypical cases, he claims, are exceedingly common, frequently giving only the clinical picture of slight tonsillitis or pharyngitis, and even without any constitutional disturbance whatever. These latent cases are largely responsible for outbreaks and epidemics of diphtheria; they are just as contagious as the acute membranous type and call for the same precautions. Tonsillitis and pharyngitis should be included, therefore, in the notifiable diseases, and at least two negative throat cultures be obtained before any patient in whose throat virulent bacilli have been found shall be allowed to go at large. While there is a disagreement of authorities as to the distinction between the diphtheria and pseudodiphtheria bacilli, the error, if any, should be on the safe side. Nevertheless, Solis-Cohen thinks that the health authorities may properly disregard the presence of diphtheria-like bacilli in the throats of healthy persons who have not been in direct or indirect contact with a case of diphtheria, membranous, or latent, and who have not themselves suffered from sore throat. Otherwise they should, in his opinion, be subjected to the same restrictions as infected contacts residing in the same house with a diphtheria patient, *i.e.* be excluded from school or work and not permitted to frequent public places till two successive cultures have proved negative. Every one who has been in contact with the patient, whether at home, at school, or at work, should be examined bacteriologically. Disinfection of fomites and terminal disinfection of rooms and their contents is insufficient and reliance thereon treacherous. Animate carriers of infection are much more dangerous than the inanimate. He would not dispense with terminal disinfection, but would postpone it until after all the members of the household have been examined bacteriologically and found free from germs.

The Lancet, June 22, 1907.

A Dangerous Dry Shampoo.—H. C. Colman cautions against the use of tetrachloride of carbon, which is now having quite an extensive use by hairdressers in some of the English cities. On one occasion it was used on a woman who felt a severe scalp irritation, but was reassured by the operator, who said she would soon feel all right. Her next recollection was that of finding herself propped up on the floor, a wet towel round her head, the window wide open, and a very frightened hairdresser fanning her vigorously with a towel. She was informed that she had been unconscious for five minutes and had been a very nasty color. Assistance was obtained and she was put to bed, where the author saw her shortly after. She had vomited severely before his arrival and she told him she felt just as she did after taking chloroform and her appearance tallied exactly with her description of her feelings. Her color was bad and her pulse was somewhat accelerated; she had a severe headache and complained greatly of nausea. During the night she vomited once more, but in a day or two she was all right again and in her usual good health. Colman then makes some observations on the chemistry and toxic properties of the hair wash in question. Some forty years ago it was introduced into medicine for headache, chorea, neuralgia, etc., but it produced ill-effects and was abandoned. Its action was found to resemble that of chloroform, the differences being explicable to a large extent by differences in physical characters (vapor pressure, solubility in water, etc.). It is important to note that all observers have found carbon tetrachloride to be more toxic than chloroform. It is more irritant to mucous membranes and is much more depressant to the circulatory and respiratory systems. During its inhalation cardiac weakness and irregularity and cyanosis have been described and after the return of consciousness cardiac weakness, headache, and mental and bodily exhaustion have been noted. Anesthesia is less easily produced and is slower in appearing than that by chloroform owing to the lower vapor pressure of carbon tetrachloride (boiling point of chloroform from 60° to 62° C., of carbon tetrachloride 76.5° C.), but it also disappears less quickly. It is probably owing to this relatively low vapor pressure that no fatalities have hitherto been described.

British Medical Journal, June 22, 1907.

Infection in Measles Transmitted by Letter.—H. R. Davies refers to the case of a man complaining only of debility, but in the eruptive stage of measles. Next day the patient, unknown to the doctor, wrote a letter to a brother who, in the usual time, came down with the disease, although he had been in contact with no one who had had the malady. It was believed that the letter had transmitted the disease from the first patient to the second, as it had been written when all the symptoms of coryza were evident and during the height of the rash.

Rumination in Man.—A. C. La Frenais records the history of a clergyman of forty years who twenty years before, while still a student, noted that after eating breakfast and hurrying a meal he frequently regurgitated food half an hour to an hour and a half after eating. No sour taste was observed; in fact, the function seemed quite natural and rather pleasant. He thought it was a form of indigestion, but there was no discomfort of any kind, and finally he came to view it as a corrective process and even to depend upon the return of hastily-chewed food. For the most part, fairly large pieces of meat only were returned. He noticed that pork of all kinds, and mutton chops especially, provoked regurgitation, and that steak, grilled or fried, frequently returned. He still experiences the same thing, but only very occasionally. Fluid at times returns to the mouth, especially after a very full meal when much liquid has been taken; it is never sour or unpleasant. So far as he has observed, the action in regurgitation is a simple reversal of the process of swallowing. There is no eructation or spasmodic feeling, and to some extent the process is under control, though mostly quite involuntary. When a portion of partially chewed beef makes its presence felt in the stomach he can, by a slight contraction of the abdominal muscles, force it into the esophagus, which automatically completes the process. He has lately observed roast pork return after two hours, still quite sweet. The only stomach trouble he remembers is some slight "heart burn" in early youth.

Referred Pain and Its Diagnostic Value.—By referred pain D. Forsyth means that variety of pain which is located to one healthy part of the body as a result of disease in another. It may be the only pain produced by the disease or it may coexist with a greater or less degree of local pain set up in the affected viscus. Referred pain can arise, however, without remote disease. Numerous illustrations of this fact are mentioned by the author. We must remember that consciousness is constantly being interrupted by stimuli coming from the skin and rarely by any from the viscera. We are therefore inclined to ascribe all our sensations to the skin and overlook the fact that occasionally the stimulus may arise from some viscus. Not only is pain referred to spinal segments of the trunk, but areas on the head and face supplied by cranial nerves may betray a similar sympathy with visceral disease. For example, soreness of the vertex of the scalp will be associated with disease of the stomach and occipital tenderness will go with ovarian disorder. Head believes that the whole body, within and without, is innervated by a system subservient to the more lowly sensations of pain and of the extremes of heat and cold. This system he calls the protopathic system. In addition, there is another system, the epicritic—distributed only to the skin and concerned in cutaneous localization, discrimination of distances between stimulated points, and the finer grades of temperature called warm and cool. Now it is interesting to note that with referred pain the skin is in a condition of hyperalgesia, but never of hyperesthesia proper—that is to say, a disturbance of the visceral protopathic sense leads to a disturbed somatic protopathic sense, but never to a disturbed epicritic sense. The author then takes up various clinical conditions illustrative of his main thesis, as, for instance, the simulation of appendicitis by the pain of an early pneumonia, etc. Very often the matter may be elucidated by a careful study of the spinal segment corresponding to the area involved. Referred pain and its superficial tenderness is limited by boundaries set in the central nervous system.

Berliner klinische Wochenschrift, June 17, 1907.

Heat Formation in Fever.—Aronsohn reviews the various theories that have been suggested in regard to the source of the surplus heat occurring in fever and the manner in which it is liberated, and details the results of experiments he has carried out since he and Sachs, twenty-two years ago, discovered the heat center in the corpus striatum. He does not agree with those who believe that the liver, brain, blood, or pancreas are sources of the excessive heat, but is of the opinion that the muscles are the site of its liberation. The theory that the muscles through increased contraction of their fibrils generate the heat of fever is also discredited, and the author describes experiments which bear out his contention that the abnormal heat formation in fever is the result of the action of proteolytic ferments on the cells of the muscle bundles. His theory of heat generation in fever is as follows: Impulses originating in the heat center are transferred through caloric or trophic nerves to the muscles; the muscle plasma sets free proteolytic ferments in abnormal amounts and these transform the vital force of the cell contents into heat.

Constitutional Forms of Lipomatosis.—Kisch says that general adiposity may be divided into two types, the alimentary and constitutional. The first of these depends largely on the amount and nature of the diet, together with the bodily exercise taken. Certain cases do not come under this heading, however, and must be regarded as the result of constitutional perversions of metabolism resulting from hereditary conditions or general disease. In some of these there may be a congenital peculiarity in cellular activity through which fat is preserved from oxidation and is deposited in the body; in others there may be a morbid alteration in the cellular decomposition processes, particularly regarding the breaking down of non-nitrogenous bodies. The treatment of the alimentary type of lipomatosis involves rigid dieting, and the daily calories may without danger be reduced to 1,100. The use of baths, mineral waters, and exercise contribute to the result. The treatment of constitutional adiposity is much more difficult and involves an improvement in the function of the blood forming organs, so that the cellular processes may be favorably modified. For this purpose resort to the iron baths and alkaline and acidulous waters, together with hydrotherapeutic measures, is of advantage, but the prognosis is never very favorable.

Münchener medizinische Wochenschrift, June 4 and 11, 1907.

Abdominal Arteriosclerosis.—Perutz says in regard to this subject that arteriosclerosis may cause severe paroxysmal abdominal pain, which may be colicky in nature or may in some cases exhibit a direct transition into attacks of angina pectoris. These attacks are usually produced as the result of spasm of the small intestinal vessels and the ensuing rise in blood pressure. The pain probably originates in the sympathetic system. In addition to the anatomical changes in the vascular system functional disturbances such as those caused by nicotine and other poisons are also capable of producing spasmodic crises of this nature. The condition is often difficult to recognize and protracted observation may be necessary to establish the diagnosis. The recognition of the condition may be facilitated by studying the effects of the administration of drugs acting on the vascular system.

Gastric Erosions.—Berger says that erosions of the gastric mucous membrane as distinguished from the ulcus rotundum may be divided into two groups. The first of these comprises the cases of erosion due to circulatory disorders and those resulting from the action of bacterial or toxic agents. In these cases the gastric symptoms do not usually occupy a very prominent place in the picture of the disease owing to the fundamental general condition. In the second group are the conditions known as Einhorn's disease, and simple gastric erosion. The characteristic symptoms of Einhorn's disease are gastric pain, weakness, and emaciation. The pain is apt to be a burning sensation, appearing shortly after the ingestion of food and lasting one or two hours. The emaciation may be extreme, as the patients refrain from food owing to dread of the pain, though they do not present the appearance of cachexia. The feeling of weakness is most pronounced after eating and goes hand in hand with the emaciation. Other symptoms, such as vomiting, anorexia, constipation, or diarrhea are not constant. The single objective symptom of the condition is the appearance of small shreds of mucous membrane in the wash water obtained from the fasting stomach. The differential diagnosis from gastric neuroses or ulcer is often difficult and the fasting stomach should always be examined in doubtful cases, particularly if the test meal shows a normal or subnormal acidity. The course of the disease is protracted and relapses are frequent. The local treatment consists of large doses of bismuth and lavage with nitrate of silver solution. The author reports two cases of the very rare condition of simple gastric ulceration (exulceratio ventriculi simplex) in which persons who had never complained of gastric disorder suddenly suffered from profuse and frequently repeated hemorrhages. Both of these cases ended fatally.

A Method for Facilitating the Expulsion of Ureteral Calculi.—Jahr describes a case in which a patient on whom a nephrectomy had previously been done was suffering from an impacted ureteral calculus on the other side.

The fact that only a single kidney was present made it highly desirable to extricate the stone through the bladder, and this was successfully done by a method which the author recommends for use in all cases of ureteral colic lasting more than twenty-four hours without passage of the stone. A special form of ureteral catheter was used, provided at its extremity with a delicate envelope of rubber, which could be distended with fluid through a separate channel in the body of the instrument. This catheter is pushed up the ureter until it touches the impacted stone; the rubber balloon is then distended with fluid and the ureter in front of the calculus is thus dilated to a degree sufficient to enable the *vis a tergo* of the urine to push it onward. If success does not follow this measure a little sterile oil or encaine solution may be injected through the lumen of the catheter in order to lubricate the ureter or to bring about relaxation of the spasmodic contraction usually present in these cases.

Reflex Laughter from Optic Stimulation.—Neustätter describes a peculiar optic reflex which he has observed in five cases and believes to be not very unusual. It consists in an irresistible impulse to laugh when the eye ground is brightly illuminated in performing ophthalmoscopy. The author believes that, in most cases at least, the element of the merely comic attending the examination of the eye ground with the ophthalmoscope may be excluded, and that the reflex in question produces an effect comparable to that caused by tickling. The sneezing sometimes caused when bright sunlight strikes the eye involves a reflex of the respiratory organs which may have something in common with the one just described.

Deutsche medizinische Wochenschrift, June 6 and 13, 1907.

The Quantitative Estimation of the Patellar Reflex.—Pick comments on the lack of uniformity that at present exists in records relating to observations on the patellar reflex and suggests a scale of intensity by means of which more accurate designations may be obtained. The normal patellar reflex he believes may be described under three heads: Weak normal, involving visible contraction of the entire quadriceps without distinct jerk; normal, visible contraction with slight jerk; and active normal, visible contraction with active jerk. In decreasing intensity the first grade is represented by a palpable but not visible contraction of the quadriceps and a jerk when the reflex is reinforced by Jendrassik's method. The next grade comprises palpable contraction by Jendrassik's method, and finally there is complete absence of the reflex when under the Jendrassik's reinforcement there is neither jerk nor visible nor palpable contraction of the muscle. In the ascending scale the first grade of exaggeration is represented by active jerk following very gentle percussion of the patellar tendon; the next by the occurrence of patellar clonus on percussing the tendon or drawing down the patella, and finally there may be a third degree of excessive exaggeration. The author suggests that these degrees of intensity may conveniently be recorded by using the figures −1, −2, etc., or +1, +2, etc., somewhat after the manner of the system employed by the oculists. He also emphasizes the necessity for using the percussion hammer in evoking the reflex.

Specific Catabolism in Cancer.—Leyden and Burgell describe experiments on a new ferment extracted from liver juice, which appears to have a selective action in producing lysis of cancer cells. In regard to the selective action of various agencies influencing the cells of malignant tumors they say that the effect of radiation with the Röntgen rays involves very slight selective action, the injection of radioactive substances is accompanied by a temporary and nonprogressive action, and in pacreatin action the selective property is very incomplete. Although the selective action of the liver ferment is pronounced, there seems but little prospect of being able to make use of it therapeutically owing to the uncontrollable nature of its action. It is suggested that the unrestrained growth of malignant tumors depends on a deficiency of the body in a lytic property that probably is specific. That is, the healthy individual possesses a ferment-like body which is absent or is not present in sufficient amount in the carcinomatous organism.

The Detection of the Simulation of Mental Diseases.—Koppen says that the detection of simulation is one of the most difficult problems in psychiatry and that whereas formerly it was the custom to consider malingering as of common occurrence, it is now realized that much greater caution is necessary in making this diagnosis than was supposed to be the case. One of the fallacies to be guarded against is the fact that in many mental diseases the tendency to exaggeration is a distinct symptom. This is especially true in regard to those diseases having a basis of hysteria in which there is a pronounced tendency to intensify the symptoms of disease and to simulate diseased conditions through a process of autosuggestion. Persons with defective heredity and degenerates also come under this class. Furthermore, the conditions under which criminals, for example, find themselves are likely through the sense of guilt, of isolation from the world, of helplessness, of dread of punishment, etc., to lead to an actual alteration of the mental state. Even if the differentiation between simulation and actual mental impairment is successfully made, the further difficulty arises of determining whether the malingerer is not at bottom mentally diseased or has in the past exhibited evidences of abnormality.

Wet Compresses and Packs.—Determann describes the technique of several hydrotherapeutic measures and the conditions under which they may be used. The application of the compress is carried out by dipping a rather thick and rough cloth in cold, warm, or hot water, and either placing it against the affected part of the body or wrapping it around it. Such compresses may be cold, warm, or stimulating. The first two are kept either hot or cold, as the case may be, by repeated changing or through the use of a rubber coil. The stimulating compresses are applied cold and are covered with a dry, poorly conducting layer, such as linen or wool. The cold packs are given by laying the patient on a sheet wrung out of water at a temperature of 12-20° C. This is quickly wrapped about the entire body and in turn a blanket is wrapped over this. Before placing the patient in the pack the forehead, eyelids, and breast should be cooled and a cold compress be applied to the head. The length of time the patient is left in the pack depends on his power of reaction and on the individual conditions. Sometimes it is advisable to transfer the patient several times to fresh, wet sheets. The indications for the cold pack comprise fever, nervous unrest, with or without fever, psychoses, and neuroses, and especially in nervous insomnia. It is used with success in diseases accompanied by tremor, cramps, or musculat spasm, such as paralysis agitans, chorea, athetosis, spastic palsies, etc. It is also excellent in exophthalmic goiter and other conditions accompanied by cardiac or vasomotor excitability. The hot pack is used in rheumatic affections, polyneuritis, renal affections, congestion of the internal organs, and inflammatory conditions of the cerebrospinal meninges.

French and Italian Journals.

Cystomata of the Ovary.—A. Cimoroni classifies the cystomata of the ovary among the mixed tumors. The elements of the endoderm prevail in them and they preserve the hereditary attributes of the cells that constitute them. The dermoid cysts are formed in great part of cells that arise from the elements of the ectoderm, and maintain the physiological activity of these layers, producing sebaceous substances and skin-like tissues. The histological examination of fourteen cystomata examined by the author show that there is considerable complexity of structure. The author has made experiments with the fluids found in these cystomata to learn whether there are digestive substances found in them that are similar to those found in the intestines. He finds that the pseudomucous contents of these cysts have some digestive power of a proteolytic nature similar to that of the intestine. The histological structure of the cysts examined by the author showed them to contain the structures found in the intestinal wall, and in a few cases fragments like the suprarenal capsule. Another showed presence of myxomatous or myxosarcomatous tissue. In all of them there were unstriped muscular fibers and cylindrical and calciform epithelium. These cysts are generally single, sometimes multiple, and often multilocular, with a distinct pedicle when intraperitoneal; when extraperitoneal they grow into the folds of the broad ligament. The contents are serous, mucous, or pseudomucous. They are lined with a single layer of columnar or cylindrical epithelium. They are benign, but sometimes undergo malignant degeneration.—*Il Policlinico*, February, 1907.

Albuminuria in the Course of Impetigo or Impetigenous Eczema in Children.—M. B. Auché describes two cases of impetigenous eczema in which albuminuria indicated the presence of nephritis. Fortunately this complication is rare. The pathogenesis of the condition is the interesting point with reference to the disease. The theory that is most generally accepted is that of infection. But infection may act in different ways. It may act by the production of poisonous substances from the life activity of the germs which are carried by the circulation to the kidneys and produce a nephritis. Again the bacteria may themselves penetrate past the lymphatic glands and be carried by the circulation directly to the kidneys, whose epithelium is irritated and nephritis results. Streptococci are then found in the circulation and in the kidneys.—*Journal Médical de Bordeaux*, May 5, 1907.

Book Reviews.

CATHOLIC CHURCHMEN IN SCIENCE. Sketches of the lives of Catholic Ecclesiastics who were among the great Founders in Science. By JAMES J. WALSH, M.D., Ph.D., LL.D.; Professor of Medical History, Fordham University Medical School, and Professor of Physiological Psychology in St. Francis Xavier's College, N. Y. Philadelphia: American Ecclesiastical Review, The Dolphin Press, 1906.

THE seven clergymen whom Dr. Walsh has selected as the subjects of these agreeable essays are: Copernicus, Basil Valentine, Linacre, Athanasius Kircher, Bishop Stensen, Abbé Haüy, and Abbot Mendel. By means of a review of the very notable contributions to science made by these investigators, the author endeavors to show that the Roman Catholic Church has been wrongly accused of having, at least at one period of its history, placed obstacles in the way of the advancement of knowledge. Whether or not he proves his point must be left to the judgment of the individual reader, but at any rate he has collected a mass of very interesting material, and has put it into very attractive form.

MEDICAL JURISPRUDENCE, FORENSIC MEDICINE, AND TOXICOLOGY. By R. A. WITTHAUS, A.M., M.D., Professor of Chemistry, Physics, and Toxicology in Cornell University, and TRACY C. BECKER, A.B., LL.B., Counsellor-at-Law, Professor of Criminal Law and Medical Jurisprudence in the University of Buffalo; with the collaboration of AUGUST BECKER, Esq.; CHAS. A. BOSTON, Esq.; Hon. GOODWIN BROWN; W. N. BULLARD, M.D.; J. C. CAMERON, M.D.; J. CLIFTON EDGAR, M.D.; JAS. EWING, M.D.; E. D. FISHER, M.D.; J. C. JOHNSON, M.D.; D. S. LAMB, M.D.; H. P. LOOMIS, M.D.; W. B. OUTTEN, M.D.; ROSWELL PARK, M.D.; J. PARMENTER, M.D.; IRVING C. ROSSE, M.D.; E. V. STODDARD, M.D.; GEORGE WOOLSEY, M.D.; J. H. WOODWARD, M.D. Second Edition. Volume Two. New York: William Wood & Company, 1907.

THIS volume continues the consideration of Forensic Medicine which was commenced in Volume I, and contains chapters on the following subjects: (1) The medicolegal consideration of wounds, including punctured and incised wounds, and wounds made by blunt instruments other than gunshot wounds. (2) The medicolegal consideration of gunshot wounds. (3) The medicolegal relations of electricity. (4) The medicolegal consideration of death by mechanical suffocation, including hanging and strangulation. (5) Death from submersion in its medicolegal relations. (6) Determination of survivorship. (7) Abortion and infanticide. (8) When medical examination or other inspection of living human body is permitted or required by courts of law. (9) Pregnancy, labor, and the puerperal state. (10) Sexual incapacity in its medicolegal relations. (11) Medicolegal considerations of rape. (12) Unnatural crimes. (13) Railway injuries; their clinical and medicolegal features. This last chapter (on railway injuries) is the one which shows the greatest amount of alteration and revision, and is one of the most important in the book; it occupies more than two hundred pages, and is a valuable and original treatise on an important subject.

The present volume, while it maintains the high standard of excellence of its predecessor, contains articles which are more likely to appeal to the practising physician. There is hardly a chapter in the book which is not of real interest and practical value to the physician and surgeon, and in some cases he will search elsewhere in vain for the information here given. Among the important features of the work may be mentioned the detailed account of the cases illustrative of the various conditions discussed in several of the chapters, the unusually numerous bibliographical references, and the table of legal cases cited in the volume.

A TEXT-BOOK OF ELEMENTARY ANALYTICAL CHEMISTRY, QUALITATIVE AND VOLUMETRIC. By JOHN H. LONG, M.S., Sc.D., Professor of Chemistry and Director of the Chemical Laboratories in the Northwestern University Medical School. Third Edition. Revised and enlarged. Illustrated. Philadelphia: P. Blakiston's Son & Company, 1906.

THIS is essentially a laboratory manual, and contains the amount of qualitative and volumetric analysis usually indulged in in first-class medical schools. In the present edition a chapter has been included on reactions in solutions in general; sections have been added on the use of indicators, and a number of new processes have been included, the most important of which are methods for the titration of borates and formaldehyde. There is an important chapter on water analysis, in which are given a few comparatively simple methods for determining the suitability of water for household uses. The book is well arranged and clearly printed, and can be used in conjunction with any general text-book.

TEXT-BOOK OF PSYCHIATRY. A Psychological Study of Insanity for Practitioners and Students. By Dr. E. MENDEL, A.O. Professor in the University of Berlin. Authorized Translation. Edited and enlarged by WILLIAM C. KRAUSS, M.D., Buffalo, N. Y.., President Board of Managers Buffalo State Hospital for Insane; Medical Superintendent Providence Retreat for Insane; Neurologist to Buffalo General, Erie County, German Emergency Hospitals, etc.; Member of the American Neurological Association. Philadelphia: F. A. Davis Company, 1907.

THIS is a translation of an elementary work intended for German medical students and practitioners who have to pass an examination in psychiatry. The first half of the book is taken up with general symptomatology, etiology, course, duration, pathological anatomy, diagnosis, prognosis, and general treatment. The remainder of the book is devoted to individual mental diseases; but as the author has omitted all clinical histories, and given only very general descriptions, the student is not likely to obtain a very clear idea of the subject. The editor has wisely omitted the Prussian procedures relating to the insane, and substituted the New York State laws and commitment forms.

WOMAN IN GIRLHOOD, WIFEHOOD, MOTHERHOOD. Her responsibilities and her duties at all periods of life. A guide in the maintenance of her own health and that of her children. By MYER SOLIS-COHEN, A.B., M.D., Instructor in Physical Diagnosis, University of Pennsylvania; Visiting Physician to the Hospital for Diseases of the Lungs, Chestnut Hill; Assistant Physician to the Philadelphia General Hospital; Physician to the Children's Dispensary of the Jewish Hospital, Philadelphia. Profusely illustrated with color plates, scientific drawings, and half-tone engravings, with manikin chart printed in colors, with an index. Philadelphia, Chicago Toronto: The John C. Winston Company.

THIS book covers a multitude of subjects, and is evidently intended to be the "guide, philosopher, and friend" of the girl, the wife, and the mother. While some of the information contained in the volume is undoubtedly good, such as the advice to consult a physician when the child is ill, much of it seems unnecessary. For instance, the illustrations on pages 122 and 123 are surely of no possible use to anyone. In one of these pictures, labeled "when true affection succeeds the first passion," we see the happy man wearing a halo (or is it the lamp globe?). In the other picture, entitled "after blind passion has subsided and nothing has taken its place," we see the man and woman, fashionably attired, and linked to each other with manacles. Now, as this book is presumably intended for the young girl, we are to suppose that at about the time when the young men are beginning to be attentive she will take down this volume, read the chapter on courtship, study these illustrations, and then decide whether Harry with the halo shall be her hero, or whether she shall suffer martyrdom with Mike and the manacles. There will also be found a full-page illustration teaching young America how to brush her hair; a page of poetry on "the perfect woman;" a cut representing "beauty and health," which certainly illustrates the truth of the dictum "tastes differ;" the author's investigations on the pulse rate of a sick child, and how it was thereby proved "that the statements as found in the text-books are incorrect" (page 309); the author's success in the administration of the Pasteur treatment of hydrophobia (page 412), and many other curious and interesting facts too numerous to mention.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia; assisted by H. R. M. LANDIS, M.D., Assistant Physician to the Out-Patient Department of the Jefferson Medical College Hospital. Philadelphia and New York: Lea Brothers & Company, March 1, 1907.

THE present number of Progressive Medicine contains chapters on Surgery of the Head, Neck, and Thorax, by C. H. Frazier; Infectious Diseases, by R. B. Preble; Diseases of Children, by F. M. Crandall; Rhinology and Laryngology, by D. B. Kyle, and Otology, by B. A. Randall. The first two chapters are by far the longest and most important, and among the sections that have impressed us as particularly valuable are those dealing with cranial tumors and abscesses, the surgery of the thyroid gland, suture of the heart, diphtheria, epidemic meningitis, and typhoid and yellow fevers. But the whole number is a good one, and there is hardly a page that will not prove of interest to the practitioner.

Principles and Application of Local Treatment in Diseases of the Skin. By L. Duncan Bulkley, A.M., M.D., Physician to the New York Skin and Cancer Hospital, etc. New York: R bman Company, 1907.

This little book is essentially a compendium of valuable practical suggestions which are not ordinarily found in text-books. It consists of four lectures given by the author on this subject at the Skin and Cancer Hospital. The principles underlying local treatment of skin diseases are discussed and then applied to various of the more common conditions. The number of formulæ and prescriptions given is not as large as one might expect in books of this kind, but, as the writer wisely states, it is better to have a few well-tried and well-selected remedies of which the application is thoroughly understood than to have a larger number which are readily changed by the claims of the most recent statements or advertisements. The book contains a complete index, and constitutes a very useful manual on the subject of dermatological therapeutics.

Manual of Clinical Chemistry. By A. E. Austin, A.B., M.D., Professor of Medical Chemistry and Toxicology in the Medical Department of Tufts College, Boston. Boston: D. C. Heath & Company, 1907.

In this handy book Dr. Austin combines in a peculiarly happy way scientific and clinical chemistry. The volume is intended primarily for second-year students, and deals with the general proximate principles of the body, the blood, milk, digestive fluids, feces, urine, and the general principles of metabolism. Naturally the subjects are dealt with in a very concise way, but the material has been quite carefully selected and sifted out, so that all superfluous matter has been omitted. Therefore, the book will be found very satisfactory by students and by general practitioners doing their own chemical tests. The illustrations are simple and helpful, and a convenient table of reagents is appended.

Pediatrics. The Hygienic and Medical Treatment of Children. By Thomas Morgan Rotch, M.D., Professor of Pediatrics, Harvard University. Fifth Edition. Rearranged and rewritten. Illustrated by numerous engravings in the text and by colored plates. Philadelphia and London: J. B. Lippincott Company, 1907.

The fifth edition of Rotch's monumental work on diseases of children needs no introduction to English-speaking physicians. Only three years have elapsed since the date of the copyright of the previous edition, and yet in this space of time so many advances have been made in the diagnosis and treatment of diseases of children that the amount of revision and rewriting required for the present issue was considerable. The care of premature infants, for example, has been made the subject of a most carefully prepared special chapter, which will be of value to every practitioner who has to cope with this most difficult problem. In the section on feeding methods we find a very complete account of the modern modification methods of cow's milk for infants' use. As may be expected in a work by Rotch, a very full account is given of "Laboratory Milk" and the methods of preparing the same. Home modification, however, receives its share of notice, and a number of methods, tables, and formulæ are given. While this part of the work is masterly from the viewpoint of the specialist, too little attention perhaps has been paid to the every-day demand of the general practitioner and to short-cut methods of making up approximately correct feeding mixtures—methods which after all will always prevail in the great majority of homes where maternal feeding is impossible. It is also to be regretted that exact directions for sterilization and pasteurization are not given. In the section on gastroenteric diseases a scientific classification of these conditions is given for the first time, tabulated on page 770. No reference is made to the spirochæta of syphilis nor to its existence in the tissues of newly-born hereditosyphilitic infants. Barring these minor defects which creep into such a vast work as this, Rotch's new volume on the diseases of childhood is undoubtedly one of the most comprehensive and most complete treatises of its kind in the English language. It is especially rich in therapeutic information, and is beautifully printed and illustrated.

The Extra Pharmacopœia. Revised by W. Harrison Martindale, Ph.D., F.C.S., and W. Wynn Westcott, M.B., Lond., D.P.H., H.M.'s Coroner for Northeast London. Twelfth Edition. London: H. K. Lewis, 1906.

This unrivaled handbook of materia medica has reached a twelfth edition, and few books have better merited such a distinction. We have repeatedly commented on this work as the successive editions appeared, and nothing good we have said of it needs retraction. This edition is larger by about 250 pages than its predecessor, yet the book remains of coat-pocket size. The type is small, but clear, and as the work is intended only for reference, and not for use as a text-book, this cannot be regarded as a fault. The drugs, official and unofficial, are arranged alphabetically. Under each head are given the source the mode of preparation, the dose, and the uses. The preparations of the U. S. P. are noted, as well as those of the pharmacopœias of Great Britain and the Colonies, and the text regarding the former has been revised in conformity with the latest edition of our Pharmacopœia. There are also a list of natural mineral waters and their indications, analytical memoranda, table of poisons, a list of antitoxins and one of organotherapeutic preparations, an index and posological table, a therapeutic index of diseases and symptoms, and various minor tables of atomic weights, drop measures, freezing mixtures, melting points, etc. Indeed, nothing is wanting to make this a nearly perfect reference book for everything relating to materia medica and therapeutics.

Manuel de Gynécologie pratique. Par J. Barozzi, Ancien Interne des Hôpitaux de Paris, Lauréat de la Faculté de Paris. Préface de M. L. G. Richelot, Professeur agrégé à la faculté de médecine de Paris, Membre de l'Academie, Chirurgien de l'Hôpital Cochin. Paris: Vigot Frères, 1907.

This new book on gynecology is intended specially for the student and for the young practitioner who has had little or no experience in gynecological work. Hence the author takes the trouble to explain in some detail many of the minor matters that are too often either overlooked or taken for granted. The first part of the book deals with "General Considerations:" asepsis, examination of the patient, different positions, curettage, tampons, post-operative complications, etc. The succeeding sections deal in order with the diseases of the vulva, vagina, uterus, tubes, and ovaries, and the peritoneum. The volume concludes with an appendix containing paragraphs on tuberculosis, syphilis, hypertrophy and atrophy of the uterus, disorders of menstruation, pelvic tumors complicating pregnancy, abortion, repair of lacerated perineum, etc. There is an ample bibliography, into which, we are pleased to note, some American and English names have managed to gain admission. Naturally, the teaching of the volume differs in some respects from that which is generally accepted here; but we have no doubt that the book will prove useful to those for whom it was written.

Surgery of the Genitourinary Organs. By J. W. S. Gouley, M.D. New York: Rebman & Company, 1907.

This important volume contains the results of the life work of the Nestor of genitourinary surgery in America. It is the concrete record of his surgical studies and experiences, and his researches into its cognate literature. The book opens with a scholarly and exhaustive study of catheters and bougies, and sounds, in which these implements are described in detail in every particular. Following chapters on chronic urethritis, bulbourethral adenitis, and orchitis, which are full and suggestive, we come to affections of the seminal vesicles, which are treated in all their phases in a satisfactory manner. On the subject of strictures of the urethra the author justly remarks that the rational local treatment is based on a correct appreciation of the general physical condition of the patient, of the cause, duration, and nature of the disease, of the form, site, and degree of constriction, and of existing complications, besides a thorough familiarity with the mechanism and care of the necessary instruments. His own classical operation, known as external perineal urethrotomy, is described. The chapter on injuries of the urethra is very complete, and the directions for treatment and operation are thoroughly up-to-date.

Much surgical wisdom is displayed in the disquisitions on retention of urine during urethritis, from urethral stricture, and in elderly men. These chapters should be read and mastered, particularly by young men. Affections of the prostate and its enlargement receive ample consideration, which is fully abreast of the times. Seeing that its author was the pioneer in prostatic surgery, and the first man to perform the operation and formulate its surgical procedure—prostatectomy—one is not surprised to find these subjects thoroughly and practically handled in these pages. Other subjects here treated are: The Bladder: its Injuries; Foreign Bodies in the Bladder; Bladder Tumors; Urocystitis: its Nature, Causes, and Effects; Urocystitis: its Management; Bladder Contracture: its Nature and Treatment; Bladder Hemorrhage: its Causes, Effects, and Treatment; Bladder Sacculation: its Diagnosis and Management; Bladder Stones: their Diagnosis and Indications for Remedial Means: Lithotomy: its Early History and Modern Adaptations; Modern Lithotomy; Lithotrity: its Development and Present Status.

Society Reports.

AMERICAN MEDICAL ASSOCIATION

Fifty-eighth Annual Session, Held at Atlantic City, June 3, 4, 5, 6, and 7, 1907.

(Special Report to the MEDICAL RECORD.)

SECTION ON PRACTICE OF MEDICINE.

Thursday, June 6—Third Day.

Election of Officers.—*Chairman,* Dr. Charles F. Hoover of Cleveland; *Secretary,* Dr. Joseph L. Miller of Chicago; *Orator on Medicine,* Dr. W. S. Thayer of Baltimore.

Observations on Plague in India.—Dr. JUDSON DALAND of Philadelphia read this paper. He spoke of the extraordinary number of deaths in different epidemics since the fourteenth century. Plague was always present in Bombay and the Tibetian border of India. The clinical varieties of plague were bubonic, pneumonic, septicemic, intestinal, and ambulatory. The majority of cases seen were in the first group. This type of the disease was restricted to polyadenitis. The second and third groups were rare as primary affections, but more or less common in the terminal stage of any form of this disease. In the pneumonic type of plague, the sputum, blood, and glands contained the plague bacillus. The disease was most often spread by the ambulatory form. The diseases with which plague might be associated or confounded were smallpox and relapsing fever. Mixed infections frequently occurred. When the plague bacillus was found in the blood, 98 per cent. were fatal. The average daily mortality was forty cases. The fever decreased on the third day. The glands involved were the inguinal and femoral; also the axillary glands. In one case the thyroid was enlarged. Plague was conveyed by rats and fleas. The excellent work done was under the direction of the Royal Pregg Institute. The method of transporting plague patients to the hospitals was referred to, as well as the disposal of the dead by cremation.

A Mixed Infection with Tertian and Quartan Malaria Occurring in a Case with Symmetrical Gangrene.—Dr. EDWIN J. WOOD of Wilmington, N. C., read this interesting paper. He said that for many years the idea had existed that there was some relationship between symmetrical gangrene and malaria. In 1880, Marsean collected many cases. The doctor had six cases; four were in one family. Symmetrical gangrene occurred without fever or enlargement of the spleen. The spots on the hands and feet were symmetrical, with dry exfoliation. The blood contained numerous tertian organisms. Three weeks later the temperature rose to 104° F., with the appearance of quartan parasites in the blood. Was there such a thing as latent malaria? This case might lead one to think so. A case of febrile tertian malaria was rare, but a mixed tertian and quartan infection was almost unknown. This patient was an inmate of the insane asylum and the question arose, Was the malaria the cause of the mental trouble, and did the malaria cause the skin lesions? If it was due to malaria, it must have been due to a toxin.

Dr. GEORGE DOCK of Ann Arbor said that the circulation of the blood in malaria was not uniform, and that the parasites gathered in certain parts. Consequently specimens of blood should be taken from different parts of the body, and even from the spleen.

Dr. W. S. THAYER of Baltimore thought that these cases reported by Dr. Wood were a most striking collection of instances of symmetrical gangrene.

The Opsonic Theory and Therapeutic Inoculation with Bacterial Vaccines.—Dr. G. W. Ross of Toronto read this paper. He said that this question was of great practical importance in bacterial diseases. By opsonins was meant certain substances which were in the blood to fight bacteria. This was expressed in an index. Bacterial vaccines were either the bacteria themselves or their products. The opsonic index in tuberculous glands was 0.7. The doctor spoke of three classes of disease in which there were variations of the opsonic power of the blood. In tuberculosis, iritis, and tuberculous cystitis, the opsonic index was persistently low. The second class included autointoxications, and the third class was general sepsis. He thought that tuberculin was of value in the early cases. He spoke of the effect of a single inoculation on the opsonic index, and referred to these toxins in germ diseases relating to a cure as well as a control of the disease.

Dr. JOHN C. HOLLISTER of Chicago spoke of the irregularities of the normal index. During the last eight months he had worked on a number of normal cases, and found the average to be one (1.0). If the technique was carried out by the Wright method, the same results would be obtained.

Dr. WOODS HUTCHINSON of New York spoke of the dose of the bacterial vaccines, varying from 0.004 mg. to 0.002 mg. He said that one should not use this form of treatment to the exclusion of other forms.

Dr. Ross closed the discussion.

A Critical Estimate of the Fermentation-Specific Gravity Method of Estimating Sugar in Diabetes.—Dr. HENRY A. CHRISTIAN of Boston read this paper. As early as the year 1861 Roberts described the yeast fermentation method for estimating sugar in diabetic urine. At the present day it was the most practical method, but how accurate was it? He had compared this method with the copper test and the polariscope. The greatest discrepancy was found with the latter, due to the fact that glucose was present. The fermentation method gave as good results as other methods. The specific gravity of the urine was estimated at the room temperature, then commercial yeast was added; the fermentation was allowed to take place until the specimen gave no reduction with Fehling's solution. The specific gravity was again taken at the room temperature, and the difference between the two readings was multiplied by 0.23 and the result was the percentage of fermentable substances expressed in the terms of glucose. Similar comparisons of normal urines to which varying amounts of pure glucose had been added were studied. He concluded that this method was a practical one. Its cost was small and compared favorably with other methods. Polariscopic examinations were expensive and not accurate for glucose alone, as levulose and butyric acid caused discrepancies.

Dr. HEINRICH STERN of New York said that the commercial specific gravity tubes varied a great deal. In regard to the polariscope, he said that glycogen in the urine would be another cause for a difference in the estimation of fermentable substances.

Dr. W. S. THAYER of Baltimore said that Dr. Christian's paper was of great clinical value. It was not easy for the general practitioner to estimate the amount of sugar in the urine, as a rule, and this simple method made it easy. Diabetic patients must have estimations made of their urine almost daily, and this method was just as good as any other method.

Dr. CHRISTIAN, closing the discussion, said that filtering the urine did not affect the specific gravity, but that boiling the urine did make a change which might lead to an error. He thought that this difference was due to alcohol being driven off from the heated solution.

Prepared and Predigested Foods.—Dr. GRAHAM LUSK of New York read this paper. He said that the normal instinct of the appetite was a good indication for the individual case. From a scientific point of view man was a machine. Two points were of importance in considering

foodstuffs. One was that a sufficient amount of proteid food should be ingested; the other was that the heat value of fats and carbohydrates should be sufficient to protect the individual. He thought that the minimum diet given out by Chittenden of Yale was far below the factor of safety. The relative food value of bread and milk, together with their cost, was considered, as well as the number of calories that were contained in two loaves of bread and two quarts of milk.

Dr. S. J. Meltzer of New York said that Dr. Lusk was the first authority on metabolism, and he personally was pleased to hear him publicly take the stand against the New Haven school.

JOINT MEETING WITH SECTION ON PHARMACOLOGY AND THERAPEUTICS.

Thursday, June 6—Third Day.

The Etiology of Acute Articular Rheumatism.—Dr. Rufus I. Cole of Baltimore read this paper. He spoke of the evidence that rheumatic fever was an infectious disease. He divided it into three groups, viz., bacterial, gouty, and metabolic. The isolation of cocci had been obtained in a number of cases. To this coccus the name of *"Diplococcus rheumaticus"* had been given. Of late years the attempt had been made to differentiate these cocci. The attempt to study them from their agglutinating properties had been unsatisfactory. The doctor had injected six different kinds of cocci into rabbits and all developed arthritis. One had an abscess of the kidney. He spoke of the evidence that the joint lesions represented metastatic foci of infection, also drew the analogy of gonococcal arthritis to that of rheumatism. He thought that evidence had accumulated in favor of the view that rheumatism was not a specific disease. It was possible that acute rheumatic fever might be a mild form of streptococcus septicemia. There was little evidence in favor of the purely toxic view. The peculiar lesions induced by bacteria did not depend so much on the variations in the kind of bacteria themselves as on the differences in the reaction on the part of the body. There was some local site of infection, such as the tonsil, from which point the germs got into the blood. Cultures from the tonsils gave pure cultures in eleven out of fourteen cases. He concluded that acute articular rheumatism might be a general streptococcus infection, the peculiar features depending upon either the peculiarities in the coccus, or more probably on the peculiar reactions on the part of the body at present included under the term "resistance of the patient."

Symptomatology and Diagnosis of Acute Articular Rheumatism.—Dr. Phillip King Brown of San Francisco presented this paper. He called attention to diseases that had acute serous membrane symptoms similar to acute articular rheumatism, such as syphilis, tuberculosis, osteomyelitis, gout, scurvy, and lead poisoning. He referred also to certain skin eruptions, such as herpes, eczema, and purpura, that might occur in these conditions. In some parts of the country, males were affected in the proportion of two to one; in other parts, three to one. Season was an important factor, as well as a low barometric pressure. He spoke of the fact that gonorrheal septicemia might be accompanied by chorea which could not be distinguished from rheumatic chorea.

The Cardiac Complications of Acute Articular Rheumatism.—Dr. Alexander Lambert of New York read this paper. He said that the cardiac complications in this disease were but symptoms. In children, cardiac symptoms predominated, while those of the joints were not in evidence. From the study of five hundred cases seen at Bellevue Hospital, no case had the joints of the hands or feet affected. Half the cases had cardiac involvement. The greatest number of heart complications occurred under ten years of age (75 per cent.), but there was an increase of cardiac complications with the number of attacks of this disease. Tricuspid valvular disease was much more common than was generally supposed (50 per cent). The mitral involvement was most striking. Aortic affections were the least common. The amount of damage to the valves was seen in the amount of hyperthropy and compensation, together with the myocarditis present. In patients below twenty-one years, the sexes were equally affected. After that age, males were more often, in the proportion of three to one. It was interesting to note in some cases that symptoms of pericarditis were seen a few days before the joint manifestations. Those cases in which myocarditis was present were the most serious.

Specific Treatment of Acute Articular Rheumatism.—Dr. N. S. Davis of Chicago read this paper. He asked the question if there was a specific treatment for this disease, and then said that one could not say that there was a specific drug for this condition, but the salicylates came very close to it. The alkaline treatment was not to be regarded as a specific, but it was very useful. Alkalies appeared to prevent cardiac complications. Only one case in thirty had cardiac trouble with this treatment. He said that the acid theory of rheumatism had no foundation. The dose of the alkalines was one dram every four hours. Salicylates in health had no effect upon the temperature. In fever, however, a fall of temperature took place in four to six hours. The drug entered the circulation as a salicylate, but just what form or combination took place was not known. In some cases the salicylates affected the stomach. Because of the stomach irritation, the sodium salt was the best. Salol was good in mild cases, but could not be given in large enough doses for the severe cases.

The Prophylaxis and General Management of Acute Articular Rheumatism.—Dr. S. Solis-Cohen of Philadelphia read this paper. He said that all were agreed that rheumatism was a multiple arthritis. The germ, if there was one, had not yet been recognized. He believed that the germs or group of germs found in rheumatism were closely related to those which harmlessly inhabited the mouth, tonsil, and throat. He stated that cold and exposure aided in precipitating an attack of rheumatism. How were cardiac manifestations to be prevented? How were the relapses and recurrences? In three ways: rest, rest, rest. The length of time for the rest depended upon the patient. The rest should be from six to nine weeks, or until all danger of straining the heart had passed. Precardial blisters helped to prevent cardiac complications, aortitis, etc. Alkalies had to be administered to the limit, and used throughout the attack. In old patients with anemia, tincture of iron was beneficial. Attention should be directed to adenoids or the faucial tonsils, as well as to the vasomotor system. Hot and cold applications were excellent. The therapeutic sweating, as in Turkish baths, was worth trying. In those cases with weak hearts, the electric light bath was beneficial. The diet was important. The intake of carbohydrates should be the lowest possible. Fleshy foods should be avoided. The patient should be put on a milk diet.

Dr. James M. Anders of Philadelphia agreed that the etiology of rheumatism was in favor of a microorganism. He thought that various conditions of the intestinal canal at times led to autointoxication, which in turn played an important part in arthritis. He spoke of the latent symptoms of rheumatism, relating to Dr. Lambert's paper, and said that he had had cases of pure myocarditis as a complication. The treatment was specific and that was the several compounds of salicylic acid, given in from 120 to 240 grains per diem.

Dr. Alfred Stengel of Philadelphia said that he wished to speak of three things: (1) The theory of acid intoxication was exploded; (2) there was an individual predispo-

sition to the disease; (3) greater attention should be given to the circulatory system. The rest treatment was good. He used plaster casts in rheumatism, and it was remarkable how the fever subsided under this treatment. In regard to cardiac complications, he thought that the serum treatment opened up great possibilities.

Dr. Woods Hutchinson of New York said that he assumed the position of the man who said, "I know that I know nothing; others don't even know that." It was not known that rheumatism was a form of specific infection. Might it not be a reaction of the tissues? He believed that calomel with soda was an excellent drug in these cases. In regard to the arthritis, he asked if it was a true arthritis? The difference between a gonorrheal joint and one of rheumatism was as great as that between day and night.

Dr. Burkhart of Indianapolis said that everyone at times had had disappointment with the salicylic treatment. He wished to speak of the hyperemic treatment, or causing a passive congestion of the joint. By placing a bandage above the joint a congestion of the tissues was produced; later a serous exudation took place, which increased the opsonins in the joint. He thought this method had a considerable curative effect.

Dr. John H. Lichty of Pittsburg spoke of the entrance of infection through the tonsils after they had been partly removed. He called it the clipping of the tonsil, and suggested that the entire tonsil should be removed.

Dr. Upsher of Richmond, Va., said that he thought the liver was back of the so-called autointoxications, and possibly it played a part in the cause of rheumatism. Rheumatism was due to complex causes.

Dr. W. H. Nelson of Milwaukee spoke of a patient who had a severe attack of coryza preceding an attack of rheumatism. The condition of the intestinal canal was important in these cases. Fermentation was often marked. He used large doses of salicylates and gave them until toxic effects were produced.

Dr. E. H. Gaither of Baltimore said that every patient with acute articular rheumatism had a margin of infiltration on the edge of the gums, practically a mild septic mouth. In children, during the second period of dentition, chorea was frequently seen, and all had infections of the mouth.

Dr. J. A. Witherspoon of Nashville, Tenn., said that he wished to sound a note of warning in regard to large doses of salicylates. He had had two cases of poisoning from this drug. Another point in the treatment of rheumatism was to give the patient comfort. He thought that hot applications and rest would accomplish this.

Dr. George Dock of Ann Arbor spoke of the myocardial changes in the muscle cells. Some cells were like giant cells. Serious membranous changes followed the use of blisters, and consequently they were dangerous. It was possible that they might add infection. He used the ice bag.

Dr. Norman Bridges of Los Angeles said that patients recovered from the joint affections if nothing was done, but the heart was the important organ to treat. He thought morphine might do as much good as salicylates.

Dr. W. S. Thayer of Baltimore said a systolic murmur meant a change in the heart muscle. Never allow a case of acute articular rheumatism to pass from observation. Watch the patient for a long time. The tonsils should be removed. In regard to the toxic effect of salicylates, he had had two such cases, and it was his rule to tell the patient to take the medicine until the pain stopped or there was ringing in the ears.

Dr. A. A. Jones of Buffalo said that the profession was somewhat at sea in regard to the nature of this disease. Many cases of rheumatism appeared to be mixed infections. He spoke of the difference between rheumatism and septic arthritis. Why was it that chorea was always associated with acute rheumatism?

Dr. Richardson of Camden, N. J., said that the only relief found in these cases was from the hot-air treatment. Was the hyperemia the cause of this improvement?

Dr. Tomkins of Charlestown, W. Va., said that the cardiac complications were more frequent when the joints of the upper extremities were involved.

Dr. Brown, in closing, spoke of the frequency of myocarditis in rheumatism. He had had twenty-two cases in children under five years of age.

Dr. Lambert, in closing, said that myocarditis followed the same law as endocarditis and pericarditis, and he was of the opinion that the salicylates did not affect the heart complications. If salicylates did not give any effect in forty-eight hours, then he changed the drug.

Dr. S. Solis Cohen, in closing, said that there was no need of the coaltar products in this disease. He thought that the salicyl-ion might be a chemical antitoxin.

Dr. Rufus I. Cole of Baltimore closed the discussion.

Friday, June 7—Fourth Day.

The Uncinarial Anemia of Porto Rico.—Dr. Bailey K. Ashford and Dr. W. W. King of Washington, D. C., read this paper. For a number of years their attention had been confined to this disease. The skin was the only mode of invasion by the parasite. Infection through the intestinal canal might be ignored. The mere presence of the ova in the feces was not a manifestation of the disease. In these cases there was what might be called a relative immunity. The initial symptoms of uncinariasis were often preceded by languor for a few months. Then pain and tenderness developed in the right hypochrondrium, together with palpalation. Little by little anemia developed, accompanied by a weak pulse. The hemoglobin was markedly reduced, varying from 20 per cent. to as low as 8 per cent. Pain was often referred to the sternum. The patellar reflexes were reduced and often absent. Circulatory symptoms were profound. Edema of the face and feet was frequently present. Cardiac hypertrophy and cerebral effusions were also present. The death rate was low. Autopsy revealed the skin sodden with fluid. The liver was never normal, but was light yellow in color, with marked fatty changes in the outer third of the lobules. One case only had deposits of yellow pigment. The kidneys were profoundly involved. They were very pale, and presented all the signs of chronic parenchymatous nephritis. In the intestinal canal, the jejunum presented the most marked changes. Chronic intestinal catarrh was always present, and the lymphoid tissues were increased. The glands at the bifurcation of the aorta were always enlarged and abundant. Changes seen in the bone marrow were similar to those in pernicious anemia. Out of 579 cases the average amount of hemoglobin was 43.9 per cent.; 15 per cent. was common. The percentage of hemoglobin was the best sign of determining the condition of the patient. Some cases had a daily rise of 1.27 of hemoglobin. In regard to treatment, they believed that iron was not necessary. Eosinophilia was the chief point of importance in prognosis. A rise in eosinophiles was a good sign; a fall was a bad one, and generally meant a fatal outcome. The treatment consisted of thymol, which caused the worms to be expelled. Betanapthol was dangerous, on account of its effect on the kidneys. The technique of counting the parasites was described.

Experimental Anemia.—Dr. C. H. Bunting of Charlottesville, Va., read this paper. He said that clinically there were two types of blood pictures found in anemia, one the so-called idiopathic, with corresponding changes in the bone marrow, and secondary anemic type. Experimentally the blood of animals could be made to simulate these types in human beings by the introduction of the same hemolytic toxin, but by different methods of injecting it. In a case of tuberculosis with secondary anemia there was a destruction of the blood cells, but the bone marrow

cells were not affected. On the other hand, in a case of primary anemia, the poison caused a reaction in the bone marrow, and this reaction was a process of neutralization. Groups and centers of cells in the marrow could be differentiated. The red cells were mature, but not nucleated. These changes might be called the normal reaction to injury. In primary anemia there was an injury to the bone marrow, while in secondary anemia the injury varied, but there was always a deficiency of the red cells. Certain secondary anemias might simulate primary anemias. The toxins in the system produced these changes.

Differential Diagnosis of the Various Types of Anemias.—Dr. Richard Cabot of Boston read this paper. He said that to establish the fact that anemia was present, it must be determined only by the percentage of hemoglobin. He spoke of pallor and its relation to anemia. A patient might be pale, but not anemic. He gave an interesting table, classifying anemias according to their cause, history, physical signs, and blood examination. There were three classes of anemia. (1) pernicious anemia, whose cause was unknown. (2) Chlorosis. He thought that it was a myth that chlorosis occurred in boys. It always was found in girls or young women from thirteen years to twenty-five years of age. (3) Secondary anemias, due to a parasite. The anemia resulting from fish tapeworm gave blood changes not unlike those found in pernicious anemia. Pernicious anemia was a disease of elderly people, past forty years, but generally between sixty and seventy years old. The onset was insidious. The physical signs were characteristic. Generally emaciation was present. Chlorosis was a rare disease. He thought that the diagnosis of chlorosis was often wrong, and that many of these cases were incipient cases of tuberculosis. One case so diagnosed was a case of exophthalmic goiter. The red cells in chlorosis were not much reduced, but the hemoglobin was low. Secondary anemia was not present in every case in which parasitic eggs were found in the stools, but when the case was well marked and had been prolonged, the eggs in the stools were significant. This form of anemia had a gradual development. That form of fish tapeworm anemia was a rare disease in this country. The blood findings did not differ from those of pernicious anemia. The differential diagnosis was made from the history of the case and the presence of the eggs in the stools.

Treatment of Anemia.—Dr. S. J. Meltzer of New York City read this paper. He said that the medical profession knew that iron, arsenic, fresh air, etc., were most frequently used in the treatment of anemia, but he wished to draw attention to some points in the treatment which marked a distinct progress. He spoke of transfusion and of the recent work of anastomosing the end of a vein with that of an artery. Direct transfusion had cured animals. The work of the Society of Antivivisection was to be deplored.

He spoke of the great work that had been done by Herter of New York in intestinal conditions, and of the anaërobic bacteria, together with the resulting fermentation causing anemia. He believed in frequent irrigations of the colon, as was suggested by Herter. Two cases of pernicious anemia were reported cured by lavage and diet. Inorganic iron was generally used in chlorosis. He believed that the struggle between organic and inorganic iron was in favor of the latter. It was as beneficial as the organic iron in the food. The question of the absorption of organic iron was an interesting one. He did not mean albuminates of iron, or peptonated iron, but the iron that was already in the body. He said that the metabolism of iron had certain features not unlike that of the carbohydrates—somewhat as glycogen was stored up in the liver and fed out into the blood. Iron certainly was stored up in the body and fed out into the circulation and tissues as it was required. This was one of the physiological factors of safety.

Dr. Theodore Potter of Indianapolis opened the discussion. He said that he had been impressed by the relative frequency of pernicious anemia in the rural districts. During the last year he had seen five cases, and four came from the country. All of these were in men—farmers—and all were over fifty years of age. He thought that this fact might point to the origin of pernicious anemia.

Dr. A. D. Atkinson of Baltimore said that he had had one case of uncinarial anemia that had made a perfect recovery. At autopsy, four years later, no lesion was found in the intestinal tract.

Dr. Eshner of Philadelphia said that he wished to bring out the difference in classification between chlorosis and pernicious anemia. He thought that some classification should be made from the blood conditions in these cases, and suggested that one might have qualitative or quantitative anemias.

Dr. Woods Hutchinson of New York said that the more one studied anemia the more one was inclined to consider it a toxemia. He believed the time would come when the term primary anemia would be abolished.

Dr. James K. King of Watkins, N. Y., said that there was a low blood pressure in pernicious anemia. He thought that colon irritation was the best form of treatment. He first cleaned the rectum and colon; then injected saline solution into the bowel. This procedure increased the blood pressure and the symptoms steadily improved.

Dr. A. H. Jones of Buffalo said that out of ten cases of pernicious anemia only two patients were under forty years of age. One was thirty-three, and the other twenty-nine years. The only anemia whose cause was known was the so-called secondary anemia. He thought that before a complete diagnosis was made the stomach should be examined for achylia gastrica. In the treatment of chlorosis, Blaud's pill was superior to other preparations, as Dr. Meltzer had pointed out. He had found occasionally in pernicious anemia that there was a marked improvement in the blood conditions from the use of arsenic.

Dr. S. R. Black of Los Angeles, Cal., said he did not believe Dr. Cabot was justified in his classification of anemias. Primary anemia should be in the class with other anemias that gave the same blood picture. He spoke of hypertrophy of the genitals and cardiovascular changes occurring in pernicious anemia.

Dr. Hobson of Parkersburg, Iowa, said that in a country practice in a town of 3,000 inhabitants he had seen twenty cases. All had had a careful diagnosis, made from the blood examinations, and it was interesting to find how frequently pernicious anemia occurred in the country districts.

Dr. Frank Smithies of Ann Arbor said that he wished to emphasize the point that Dr. Cabot made regarding the examination of the blood in the final diagnosis. The treatment was rest, fresh air, and diet. The patients were placed in the sunlight for eight hours. The gastric condition had to be corrected by careful feeding. At critical periods food was given in spoonful doses. He had found that the blood pressure was low—one case as low as 60 mm.—but he thought that no therapeutic conclusion was to be drawn from the blood pressure. In regard to the fact that pernicious anemia was seen in farmers, he thought that it was due to some geographical condition rather than any condition of the farmer's life.

Dr. Norman Bridges of Los Angeles, Cal., said that there was only one drug in the treatment of chlorosis—calomel in tonic doses, one-fifth to one-thirtieth of a grain. This gave better results than iron preparations.

Dr. Bunting, in closing, spoke of the experimental pernicious anemia and of the various causes. He thought that the great majority of cases of anemia were due to the same cause, which at present one was unable to separate.

Dr. Cabot of Boston said that the question of classification was one of convenience. In some anemias the cause was known, in others unknown. He spoke of the work done

by Dr. Ashford in ridding the whole island of Porto Rico of the hook-worm. He said that Dr. Ashford had found the cause of uncinariasis. He did not agree with Dr. Meltzer that intestinal fermentation was the cause of pernicious anemia.

Dr. Meltzer closed the discussion.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held May 21, 1907.

DR. WARREN COLEMAN IN THE CHAIR.

The Clinical and Autopsy Records of a Case of Paraplegia in Consequence of an Aneurysm of the Arch of the Aorta; Demonstration of Specimen.—Dr. BOND STOW reported this case and showed the specimen. (See page 59.)

Some Sources of Error in Gastric Diagnosis.—Dr. CHARLES S. FISHER read this paper. He said that as most of the serious questions in gastric diagnosis arose from suspected conditions at the pylorus and as most exploratory operations were made to decide conditions involving this region, it was natural that any hint bearing upon this region should be of interest. The presence or absence of a tumor mass was often a matter of such doubt in these cases that little reliance could be placed upon the tactile condition and the imagination of the individual examiner, both very uncertain quantities. Granted that these faculties were developed to the fullest measure, they were often rendered useless by the erratic conduct of the pylorus itself. Unless the sphincter was absolutely destroyed by new tissue infiltration, it would assume a changeable consistency dependent upon the vigor of manipulation, the length of examination, and its general irritability; that was, what one examiner might feel as a contracture at one examination might be a relaxation of the one following. In this respect the first examination always had the advantage, for the pylorus could tire out very easily. No two examinations should be made in immediate succession for this reason. A peculiarity of pyloric new growths in any stage, but of value only in the early period, was the tendency which they had to induce spasmodic strictures of the esophagus in some instances. He said they had been taught to believe that in cases of pyloric stenosis with accompanying dilatation, the differential diagnosis between malignancy and benignancy depended largely upon the duration of the illness, all other things being equal, and it often happened that upon this point they were forced to the conclusion that a given condition of this character was benign only to find that at the operating table the usually accepted evidence had been misleading. Instead of connective tissue contraction they found a very small nodule, very hard in consistency, causing a partial obstruction sufficient to give all the characteristic subjective and objective evidences of retention. In these cases the history was one of long duration, and instead of a lack of secretion there was a hypersecretion in its most active sense. The organ was in a state of overstimulation due to the partial retention. It was impossible in these cases to avoid error, for there was no way to determine the presence of a growth by the usual methods and the history itself could only mislead. There was another condition in which the pylorus had resolved itself into a rigid tube, patent for all ordinary semiliquid diet. In these cases there was no great food retention and no dilatation whatever. The stomach not only emptied itself, but almost constantly contained bile, which was misleading. A suspicion of the actual condition might be aroused by the fact that it was very difficult to determine the size of the stomach by percussion after filling with water or by insufflation. Condition in the gall-bladder, duodenum, kidney and appendix might be obscured by giving rise to gastric symptoms, in which the pylorus played in reality a secondary role. Among the remote influences which might affect the pylorus and occasionally direct attention to it as the seat of some organic lesion were sudden changes in temperatures and sudden changes in mental disposition, sudden fits of temper. Examination of the stomach during the intervals would reveal nothing abnormal, and they must rely entirely upon the history for the diagnosis. He thought that it was hardly necessary to refer to the interchangeable nature of prolapsed kidney and pyloric symptoms in those cases where no pronounced symptoms were referable to either. It sometimes happened, however, that a kidney prolapsed to the first degree might give rise to actual spasmodic pyloric attacks. There were two conditions distinctly connected with the nervous system which at times gave rise to such pronounced acute gastric symptoms as to mislead; though of different origin, they gave rise to acute pyloric spasm with all its accompanying symptoms. He referred to conditions of temper, and to the state of post-prandial hysteria, or nervous excitation beyond the control of the individual affected. In closing he called attention to two very common conditions of the fundus, atony, and catarrh of the stomach.

Dr. ROBERT T. MORRIS said that he was glad to hear Dr. Fisher call attention to the influence gallstones played and, in this connection, he wished to ask members of the section who were engaged in post-mortem work if they knew the proportion of cases in which adhesions from the bile tract engaged the pylorus, no gallstones being present. He said that he had had occasion to operate upon a number of such cases; there was a given proportion of the cases where the obstruction was due to bile tract adhesions. They should be more alert in diagnosing these cases, because a fairly large percentage of his patients with pyloric stenosis were patients with bile tract adhesions which engaged the pylorus. There was no other cause for the obstruction. The percentage was large enough, however, so that they should learn to distinguish these cases. The post-mortem showed that they had adhesions to some extent, probably not important in most people, and probably some did not even suspect that they had any adhesions. In some cases, however, they caused symptoms of pyloric obstruction. Another point he wished to speak of was gas collections in the hepatic flexure occurring in many cases, and which could be explained in two ways: first, the effect of these bile tract adhesions engaging the hepatic flexure, and they were certainly due to gas accumulation with the peristalsis affected; and secondly, to an entirely different group of cases. In involution of the appendix there was a hyperplastic replacement which contracted and engaged the filaments of the nerves, and impulses were transmitted from the base of the appendix to the lumbar plexuses and even to the semilunar ganglion. Meissner's and Auerbach's plexuses were acted upon, and there was a distention of the hepatic flexure, during which the involution of the appendix was under way. He presented three specimens which were removed from patients who had gone the rounds for from five to ten years. In the first there was no mucosa or muscularis, nothing being left but this hyperplasia and nerve filaments. These patients must have had symptoms. In the second specimen, the patient from whom it was removed suffered for ten years, and here there was an irregular involution. The nodes represented mucosa, and there was an internode replacement of muscularis and lymphoid tissue. In the third specimen, the appendix was undergoing involution. These three specimens represented appendices found frequently in people with intestinal dyspepsia of obscure origin. In a certain proportion of cases, a loose kidney presses directly upon the

pylorus. He had found such cases, and had relieved them by fixation of the kidney. Very often he found that eyestrain was a cause of obscure gastric disturbances in patients sent to him for operation. He now made it a rule to work out this possible factor, or at least to get negative testimony upon this point. Ophthalmologists have reported upon the muscular balance, not upon the sight. There was a large enough proportion of cases who had avoided operation every year to make it necessary for them to have negative evidence upon this point. In neurotic patients wtih gastric disturbances, he asked to what extent were the gastric symptoms precipitated by the neurotic condition and to what extent by the toxemia. This was an extremely difficult point to work out in his particular field.

A Clinical Study of Gastrosuccorrhea.—Dr. Henry S. Patterson read this paper. In twenty-three cases there was only one female. Excessive use of tobacco occurred in four cases, while alcohol was a factor in only one case. Occupation seemed to play an important part in all the cases. The one etiological factor which made an indelible impression upon them was the practice of masturbation. In reviewing these cases there seemed to have been present all the elements which were generally recognized as active in producing impairment of nervous function. Another element was the effect of the individual's knowledge that a stomach tube was to be passed, as well as the mechanical irritation of the tube itself. In 413 cases in which gastric analyses were made, a continuous flow of gastric juice was found in twenty-three cases in which they believed they could exclude ulcer and cancer. In sixteen of the cases gastroptosis was present; in three its condition was not noted, while in the remainder the examinations were not sufficiently exhaustive to be conclusive. Of these sixteen cases seven showed a large amount of mucus, six had a moderate degree, and statements as to the others were indefinite. In the cases in which gastroptosis was not found or noted, in three mucus was very abundant, in two it was present in moderate amount, in one it was not noted, and in one not found. Whether these were cases of acid gastritis or not they were not prepared to state definitely. The amount of juice in these cases varied from 30 to 200 c.c. The amount of free hydrochloric acid varied from ten to ninety-two. There seemed to be no relation between the amount of juice and the amount of free acid. The color of the juice was bright green, yellowish-green, yellow, or of the appearance of clam juice, but they had not been able to find any relation between the color and the degree of acidity. In conclusion they emphasized (1) that chronic gastrosucchorrhea with atony or acid gastritis occurred in individuals whose environment and habits deranged the nervous integrity, and that masturbation was a notable causative factor (2) That it was a fairly frequent phenomena in gastric disorders and would be found more often were methods of case study more complete. (3) That the finding of bile in the fasting juice was a fairly constant characteristic.

Dr. W. A. Bastedo said that Strauss regarded forty c.c. as the minimum pathological amount of gastric juice in a fasting stomach, but Dr. Bastedo believed that they should take the stomachs as they found them, and that there might be a continuous secretion of gastric juice, and yet none at all might be found. What figure to take was hard to say. With regard to masturbation, that was one of the causative factors of neurasthenia. Take, for instance, students who were run down by overwork and worry, between fifteen and thirty years of age, they became very neurotic; in their fasting stomachs a great deal of gastric juice was to be found, especially during the more neurotic periods. Masturbation was a causative factor in causing a similar neurotic condition and, therefore, produced a gastrosuccorrhea. In his work he liked to give a meal to satisfy the appetite, or the demands of the appetite for food. He then washed out the stomach as thoroughly as possible in about an hour and a half or two hours, assuming that enough by that time had passed the pylorus to satisfy the appetite on the part of the patient. He then waited one hour and then determined if there was any gastric juice. If so, he assumed that the stomach was secreting with no stimulus from appetite or from food. In his cases of gastroptosis he found a great many secreting a great deal of gastric juice when he could not get the test with iodine for starch or other evidences of food remains. In some cases of atony there was some gastric juice present without gastroptosis. Dr. Bastedo recalled the work of one man who found in cases where there was a great deal of gastric juice, or a moderate amount in a fasting stomach, that there were many in which ulcer was present. There were twenty-eight cases in which the surgeon could not find evidences of ulcer; yet upon operation ulcers were found in every one of them. The type of the contents was very interesting; it did not seem to be a normal gastric juice. In some cases there was no pepsin present; two out of eight cases were reported with no pepsin present. The hydrochloric acid varied greatly as well, and it was interesting to note the differences between the acidity before and after a meal; in some cases the acidity was the same.

Dr. F. V. Goodridge said that he doubted that gastrosuccorrhea could be considered as a primary condition, but as secondary to one which increased the irritability of the gastric glands and caused them to secrete when they would otherwise be quiescent. These diseases were a mild form of myasthenia which through delayed digestion caused stagnation and consequent fermentation. Ulcers and erosions, either recent or healed, with the formation of scar tissue, might act as a direct irritant to the gastric mucous membrane. A pyloric obstruction from any cause and a hyperacid gastritis, the latter very important, were also etiological factors. In upwards of 500 cases of gastric disturbance he said he had only seen eight which had the chief objective symptom of gastrosuccorrhea, that was, the presence of over thiry c.c. of gastric juice in the fasting stomach without food remains. In none of these could the foregoing diseases be excluded. Boas grouped together the symptoms of the disease as follows: *Subjective:* Pyrosis, sour belching, occasional vomiting of intense sour material preceded by severe pain in the stomach and back, increased hunger and thirst and constipation. *Objective:* The patient was poorly nourished, the abdominal tenderness varied from severe and localized pain in the epigastrium to complete absence of pain; the greater curvature was generally found below the umbilicus on percussion and succussion. The other abdominal organs were normal and the most important symptom of all was the presence of over fifty c.c. of brown, green, or colorless gastric juice in the fasting stomach. There was a symptom which objectively and subjectively would fit the condition above mentioned. Reichmann, who first called attention to the disease, considered it a rare condition. Riegel, on the other hand, numbered his cases by the hundreds and Jaworski found it in about twenty two per cent. of all his stomach cases. The French authors, with the exception of Hayem, believed it was a primary and relatively frequent disease, in which conclusion Zweig agreed. Einhorn had seen eight cases in eight years. Boas considered it in almost every case to be an accompaniment of other diseases, while many others believed that it did not exist as a morbid entity. This was an extraordinary divergence of opinion, but it seemed to Dr. Goodridge that the burden of proof was in favor of the negative side of the case.

Dr. Henry S. Patterson said that he had purposely left out many points in his paper. He did not touch upon the symptomatology or therapeutics. At the College

of Physicians and Surgeons last year some very interesting investigations were made on dogs which had a most important bearing on therapeutic applications. Experiments were made to determine the effect upon the acidity when food was introduced in different degrees of moisture; they determined that the more water they gave with a given amount of meat or other food material the greater was the acidity of the gastric juice at a certain time afterwards. They found, however, that if they gave this water at intervals between the meals, not sooner than one hour before, and not earlier than one hour after the meal, no effect was made upon the juice other than diluting it. It was also found that olive oil was instrumental in bringing about an alleviation of the symptoms. Olive oil inhibited the secretion of hydrochloric acid. The use of belladonna was also advantageous.

Philadelphia County Medical Society.

At a stated meeting held June 12 a "Symposium on Opsonic Treatment" was held. Dr. Benjamin A. Thomas read a paper entitled "Variability and Unreliability in the Determination of Opsonic Indices." He pointed out the difficulty of the technique, the time required in its execution, and the necessity for the utmost precision in carrying it out. Great care is requisite in securing proper emulsions and the personal equation is a not unimportant factor in the result. By reason of these facts the opsonic principle, in its present form, is not susceptible of general application in clinical medicine. Dr. Jay F. Schamberg presented a communication entitled "Preliminary Report Upon the Use of Bacterial Injections in Diseases of the Skin." He demonstrated a case of sycosis vulgaris in which remarkable results were obtained from injection of bacterial emulsions of the staphylococcus after long-continued treatment by various other means had failed. He exhibited a second case of sycosis vulgaris in which also good results were obtained, though not so brilliant as in the first case. In a third case of eczema with complications, improvement in the secondary infections took place. Dr. Schamberg cautioned against the indiscriminate employment of bacterial emulsions in the treatment of disease, pointing out that they could be expected to prove useful only in cases of circumscribed infection. Dr. D. H. Bergey read a paper entitled "The Nature of Opsonins, and the Limitation of the Use of Bacterial Infections." He stated that the opsonins are substances, sometimes present normally, but whose production is stimulated by the injection of emulsions of the bacteria whose effects are to be antagonized. They act upon the bacteria in such a manner as to make them more readily the prey of the phagocytes circulating in the blood. The action is in every instance specific, each bacterium producing the opsonins useful in counteracting the effects of the respective microorganism. Dr. Nathaniel H. Gildersleeve presented a communication entitled "The Technique of the Determination of the Opsonic Index, with Remarks Upon the Value of the Same." He demonstrated the method of determining the phagocytic activity of normal blood with respect to the infecting organism under observation, and comparing with this the phagocytic activity of the patient's blood for the same organism. An emulsion of a culture of the organism in question is injected and the phagocytic activity of the blood is studied further. When the conditions are favorable a so-called negative phase of lowered resistance develops first, and this is soon followed by a secondary positive phase of increased resistance. Injections of increasing strength are repeated after varying intervals, but never during the negative phase. Dr. Gildersleeve expressed great confidence in the utility of the procedure from both the prognostic and therapeutic standpoints. Dr. A. A. Uhle read a paper entitled "Preliminary Report Upon Results of Opsonic Treatment in Various Clinical Conditions." He reported cases of acne, gonorrhea, and suppurative joint-disease with sinuses, some of which yielded good results to opsonic treatment. In some instances treatment was instituted without preliminary study of the opsonic index, but it was found that the treatment could be employed more intelligently and more successfully if this index were always obtained before giving the injections.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

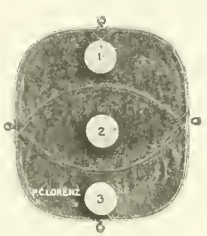
New Instruments.

A NEW ABDOMINAL ICE-BAG.

By ABRAM BROTHERS, B.S., M.D.,

NEW YORK.

The general practitioner of medicine, as well as the operator doing abdominal surgery, has frequent use of local refrigeration in cases of intraperitoneal hemorrhage or intestinal hemorrhage from typhoid fever, traumatisms, ectopic gestation, etc. Similarly in conditions of general peritonitis of puerperal or postoperative origin, cold to the abdomen is indicated. The ordinary ice-bags are usually too small, when used singly, and uncomfortable when two or three are applied at one time. The ice-coil has been a much neater and cleaner method of applying cold to the abdomen. Unfortunately it requires a multiplicity of pitchers, pails, etc., and, in spite of the constant supervision of nurses, it is apt to get out of order and not keep the abdomen continuously cold.



In order to overcome these objections I have had constructed an ice-bag consisting of three separate bags so joined as to readily adapt themselves to the contour of the abdomen. The lightest rubber has been selected and the caps are made of aluminum. The size of each bag is so arranged that an even weight lies on the abdomen at nearly every point, and patients do not complain of discomfort while the bag is in use.

By means of a tape the bag can be fastened to the abdomen and will not be displaced even by delirious patients. Once every hour the ice is replaced. By means of a suction syringe the ice-water can be sucked out and freshly cracked ice introduced into each ice-bag without removing the bag from the abdomen, and with the minimum of disturbance. The bag is manufactured by P. C. Lorenz of this city.

The Intractable Menorrhagias of Arteriosclerosis of the Uterus.—Robert L. Dickinson says that in a case of excessive and debilitating flow at the monthly periods in patients between thirty-five and forty-five years old, cancer, fibroid, polyp, and fungus endometritis, are to be considered. There is no cauliflower cervix, tumor, or much enlargement. Ergot, hydrastis, douches, and rest all fail. Curetting shows no suspicious scrapings; the bleedings continue. It is then certain that submucous fibroids too small for detection by bimanual touch, or arteriosclerosis is present. The uterine cavity should be obliterated or the uterus removed. This will depend upon both the condition of the uterus and the patient. Most incoercible menorrhagias indicate hysterectomy, and occasionally a case calls for panhysterectomy. Hemorrhages are then arrested and the secondary anemia may be successfully treated. "Neurasthenic" manifestations will be relieved in those cases in which the arteriosclerosis has been uterine, but will be only lessened when the vascular change is general.—*Brooklyn Medical Journal.*

THE CLINICAL COURSE OF GASTROPTOSIS AND ITS TREATMENT.*

By GEORGE ROE LOCKWOOD, M.D.,

NEW YORK.

I HAVE taken for the subject this evening The Clinical Course of Gastroptosis, for the reason that this disease is one of the most common which we are called upon to treat, and, if I might be allowed to say so before this Society, a disease which is not thoroughly understood by the profession at large. As to its frequency, in my last two thousand patients I have encountered this disorder in 351 cases, making 17.5 per cent. of the total number of gastric and intestinal cases due to gastroptosis. This is more than twice the frequency of gastritis, the latter disease being only 8 per cent. Now, of course, 17.5 per cent. of all dyspeptics do not have gastroptosis, and the only inference possible is that the unrelieved cases filter through the hands of the family physician and come to the specialist for relief. In no other way would it be possible to have so great a proportion of these cases. For this reason I am bringing the subject before you for discussion this evening.

On analyzing the histories of these 351 patients, it becomes evident that there is a great similarity in their clinical histories, so that it may be asserted that gastroptosis runs a course which is typical and characteristic, and one which can be divided into successive stages. Instead of presenting a statistical analysis of these histories and a detailed account of the various symptoms, I thought it would be better to take a typical history of one of these patients, and go over the symptoms and the development of the disease as illustrated by this case, and I have selected the history of a patient which presents a perfect clinical picture of the disease and is characteristic in every way of these cases.

CASE.—Young unmarried lady, 27 years of age. Patient was a delicate, undernourished child, although free from serious illnesses. When 15, she noticed that from time to time, especially after physical or nervous fatigue, she suffered from heartburn, gas in the stomach, and occasional distress after meals. When 18, she entered upon an active social life, and these symptoms became continuous and severe. She had more or less constant gas in her stomach, distress after meals, occasional heartburn. She lost weight and became very nervous. The bowels became constipated. The more she dieted, the worse she became.

This is a perfectly typical, straightforward history of the course of gastroptosis, in all its essential details. Let us examine these various statements more in detail.

"She was always a delicate, undernourished child."—This is the ordinary history of the patient before the advent of gastric symptoms, and this condition of subnutrition and nervousness may be said to constitute the preliminary stage of the disease. There is gastroptosis, but no atony. I believe it is possible to pick out in childhood those who are liable to develop symptoms of the disease later in life, and to inaugurate a prophylactic treatment so as to minimize such a liability. The method of diagnosis and the treatment will be alluded to later.

"Although free from serious illness."—A number of pathological conditions have been considered as possible causes of the disease, but I have never found any one of these worthy of serious consideration. Meinert has considered chlorosis a cause; this is not borne out by my histories. In none of the cases has gastritis seemed to be an etiological factor. As regards lacing, upon which so much has been written, I have not found tight lacing to be a cause in any of the patients; and furthermore, I have found that the modern straight-front corset does these patients more good than harm. While not advocating tight lacing, my feeling is that we can absolve it from all blame in the formation of gastroptosis.

"When 15 she noticed that from time to time, especially after physical or nervous fatigue, she suffered from heartburn, gas in the stomach, and occasional distress after meals." *A distressed stomach will do its work without symptoms, unless it becomes atonic, to which it is by nature predisposed.* This is the keynote of the entire situation, and cannot be too strongly emphasized.

At first there are occasional periods of atony, induced by mental or physical fatigue, and which one readily recovers from as soon as the cause is removed. These symptoms in this stage of temporary atony are: (1) Gas on stomach; (2) distress after meals; (3) occasional heartburn.

If patients live within their physical and nervous limitations they do not suffer. If they transgress, they have these symptoms. As the case progresses, these symptoms become more and more readily induced, and more severe. Moreover, as the case progresses, the symptoms tend to become more distressing, so as to lead finally to semi-invalidism.

"When 18, she entered upon an active social life, and these symptoms became continuous and severe." Now starts the third stage of the disease.

First stage: Gastroptosis alone—no symptoms.

Second stage: Gastroptosis—temporary atony—intermittent symptoms.

Third stage: Gastroptosis—permanent atony—continuous symptoms.

As noted before, the symptoms of atony, gas, heartburn, and distress were coming more and more frequently under temporary fatigue. Now, under the increased physical and nervous strain to which the patient was subjected, the atony becomes perma-

*Read before Bellevue Alumni Association, April 3, 1907.

nent, and the symptoms will last with reasonable certainty until the patient is put on a rest cure.

It may seem that the fatigues and nervous strains of a social life are inadequate to produce such distressing results; but patients with gastroptosis have poor resisting powers; they cannot do what other people do without suffering evil consequences, and they must be treated as a class by themselves.

In this case, the demands of a social life were sufficient to cause a continuous atony of the stomach, with its attending symptoms. In other cases, it would be some other definite nervous or physical strain.—A mother may lose her child; a lady will lose her money and have to teach; another will have a fright in a runaway accident, or will have to nurse a sick husband or child; another will have an unfortunate love affair. In 90 per cent. of my cases such a definite cause has marked the onset of the continuous symptoms.

"She had more or less constant gas on her stomach, distress after meals, occasional heartburn." The gas is a constant factor. Given a thin woman with constant gas, always suspect gastroptosis in its atonic stage. This gas is often spoken of as due to fermentation, and the patient in consequence is shut off from starches and sugars. Except in cases of pyloric obstruction, with enormous quantities of prolonged food retention and with a reduction in the amount of hydrochloric acid, as in some of the malignant cases, I am confident that fermentation in the stomach is a myth. Would that the name could be totally expunged from our records, in the treatment of our patients. You cannot make the gastric contents from these patients ferment. You may mix them with sugar, with syrup, with starch solutions, and keep them in proper apparatus, such as a saccharometer or Strauss fermentation jar, for hours and days, and they will not ferment, and you cannot make them do so. Test breakfasts are sent in mailing bottles or by express from distant parts of the country, without a sign of fermentation even after days.

I have aspirated the gas from the stomachs of these patients by catching the gas in a deflated toy balloon tied on the end of a stomach tube, and on analysis of this gas found no CO_2—merely atmospheric air. Again, the higher the gastric acidity in these cases, the more the gas. In other words, the more sterile the contents, the greater the so-called fermentation; which is, of course, an absurdity.

The *distress* regularly depends upon the amount of gas, and the quantity of the food. The distress due to gas is relieved when the patients raise it, leaving them in comfort. It does not depend either on the quantity or the quality of their food, but comes after anything simple, as well as anything indigestible. It is important to remember this in the dietetic management of the case. It has no relation, furthermore, with the time of the meals. If anything, it is more marked in the fasting condition. The distress caused by the quantity of the food is more of a loaded feeling in the stomach. The quality of the food makes no difference; it is the purely mechanical result of putting a certain weight of food into the stomach, and will appear in equal severity with a pound of water or a pound of meat.

Many of these patients have been put on large quantities of liquid food, and especially on large quantities of water. This, as will be seen later, is the worst possible treatment for these cases. Many stomachs are ruined by the attempt to flush the system, and advice on this point is not lightly to be given.

Heartburn almost regularly accompanies these cases, and is directly due to atony. The symptoms are usually more pronounced three or four hours after meals, when the stomach begins to empty itself.

"She lost weight and became nervous."—Loss of weight is a constant factor, and is proportionate to the increasing development of the disease. In some cases the patients seem to eat enough to nourish them, though they grow thin. The cause for the lack of nutrition cannot, in these cases, be determined; in other cases, the lack of nutrition is directly traceable to a starvation diet to which they are subjected, often, I am sorry to say, by medical advice. One article of diet after another is cut off, and practically nothing left but slops and liquid food. The thinner they are, the more the gastroptosis and the atony progress, and the worse they get. You cannot improve these patients even to the least degree unless you improve their nutrition.

Neurasthenia, with all its varied symptoms, is proportionate to the advance of the disease, and contributes a great variety of symptoms of increasing severity. Many of these cases are considered almost hopeless invalids.

"And the bowels become constipated."—This is regularly due to atony of the colon, often complicated by a sagging of the colon in its transverse portion. The flushing of the colon in these cases usually brings large masses of mucus in strings, and this mucous colitis, or better, "myxoneurosis," is perpetuated by the constant use of cathartics to which these patients are addicted.

"The more she dieted the worse she became."—I cannot do more at the present time than to emphasize this point. Nothing is worse for these patients than to allow subnutrition; nothing worse than liquid food; nothing worse than large quantities of water; and yet these errors are of common occurrence in the treatment of these patients. I will revert to this topic under the head of the treatment of the disease.

Physical Examination: Tall, slight, delicate girl; weight, 94 lbs., clothed. The habitus enteroptoticus is present. The lower curvature of the stomach lies 8 cm. below the navel by succussion, by scratch percussion, and by inflation; gastrodiaphany not employed. The upper curvature is not located. In the morning fasting state, 40 c.c. opalescent fluid reacting to congo, withdrawn; total acidity, 40; free hydrochloric, 14; no food remains. Test breakfast in one hour showed 130 c.c., separating into two layers, the upper one-third of clear fluid, a lower two-thirds in depth of well digested food remains; slight admixture of gastric mucus; total acidity, 62; free hydrochloric, 28. The colon is atonic in its ascending portion; irrigation brings strings of mucus. The lower border of the liver is palpable ½ in. below the costal margin in the mammary line; its edge is apparently normal. The right kidney is ⅓ palpable. Physical examination otherwise negative.

Now let us take up a few of these statements seriatim, and discuss them together.

"The habitus enteroptoticus is present." By this we mean the long, narrow thorax and abdomen, and a costal angle under 90 degrees. The sharper the costal angle, the greater the disposition to splanchnoptosis. I regard the enteroptotic habit as one of the most important conditions in gastric pathology. Patients of this class are regularly predisposed to functional disturbances of the stomach and bowels, from which those with broad costal angles are exempt. They are born handicapped in life. These are the patients who develop gastric distress regu-

larly under strains, mental and physical, and who have a lowered resistant vitality. Stiller calls this condition "congenital universal neurasthenia," and with this view I heartily agree. It is a congenital sign of physical degeneracy from which patients suffer throughout their lives. I believe that children who have this sharp costal angle should be brought up differently from others, so that the tendency to neurasthenia and gastric disorder may be minimized.

"The lower curvature of the stomach lies 8 cm. below the navel by succussion, by scratch percussion, and by inflation. Gastrodiaphany not employed."—The simplest method of locating the lower curvature is by determining the lower boundary of the succussion sounds elicited by tapotement. This is readily done, as these patients usually have thin abdominal walls, and the displaced stomach is somewhat superficially located.

I do not now enter into a discussion as to whether these succussion sounds are pathognomonic of atony, but I merely speak of them in connection with the location of the lower stomach boundary. It is important to remember that a stomach filled with gas may not give succussion sounds, and therefore always examine for this sign before the stomach is inflated.

Scratch percussion is also a valuable method for localizing the lower border. The bell of the stethoscope being placed in the epigastrium, gentle stroking is made, from below upward, until a line is reached past which its sound becomes loud and harsh.

Inflation is perhaps the most certain of all the methods, and if employed to a reasonable extent (ulcer and carcinoma being excluded), is devoid of danger. It is never necessary to inflate sufficiently to cause pain, nor should inflation be to such a degree that the stomach is seen to rise as an inflated bag, and bulging out the abdominal wall. It is merely necessary to employ a moderate inflation, so that tympanitic sounds by percussion over the stomach are clearly brought out. Even with this moderate inflation it is possible to see the lower curvature ascend and descend during respiration, if a strong light is thrown obliquely across the body of the patient so as to intensify the shadows.

For the purpose of inflation I regularly employ a level or scant teaspoonful of bicarbonate of soda and one-quarter of this amount of tartaric acid. I have never had occasion to regret these quantities.

Gastrodiaphany to my mind is absolutely inaccurate and misleading, either with or without fluorescent media, and I have long since abandoned its use.

"The upper curvature was not located."—The determination of the position of the upper curvature is not necessary. There are large gastroptotic stomachs, and there are small gastroptotic stomachs, and the size of the stomach has nothing to do with the case. Small stomachs by inflation may be determined in all their dimensions, but the upper curvature of the larger stomachs lies so nearly under the liver that it cannot be determined, and therefore I have found that no attention need be paid to the vertical dimensions of the stomach.

"In the morning fasting state, 40 c.c. opalescent fluid, reacting to congo; total acidity, 40; free hydrochloric, 14; no food remains."—The examination of the fasting stomach has been very much neglected in clinical work. It is often as important as the examination of the test breakfast itself. If fasting stomachs were more frequently tested, the confusion regarding the term "dilatation of the stomach" would not be as great as it is at the present time.

By "dilatation of the stomach," if we use that unfortunate term at all, we should mean merely one thing, namely, pyloric stenosis with food retention; and even then the term is a bad one, because many cases of pyloric stenosis are not large stomachs at all. We find in the milder cases of pyloric stenosis in the fasting state, hypersecretion only. That is, we withdraw with 100 to 200 c.c. of acid gastric juice without food remains. This is in the milder cases. In the severer cases we find not only the hypersecretion, but an admixture of food remains left from the dinner of the night before. We may consider, therefore, fasting hypersecretion as the first evidence of pyloric obstruction.

Now, these cases of gastroptosis have no mechanical hindrance to food exit. A great deal has been said and written about sharp kinks in the duodenum, occurring in gastroptosis, inducing a mechanical hindrance to food exit, and about the so-called arteriomesenteric constrictions, where the root of the mesentery, containing the large blood-vessels, is pulled downward by the downward displacements of the small intestines and compresses the third portions of the duodenum. Also, it is said, that these stomachs are so weak in their muscular power that they never become completely emptied. For these three reasons—duodenal kinks, arteriomesenteric constrictions, and extreme atony—it is said that symptoms of mechanical obstruction are present. To determine this point I have examined fasting stomachs of 200 consecutive cases of gastroptosis and have obtained

0 to 25	c.c. liquid contents,	170 cases—85	p.c.
25 to 50	c.c. liquid contents,	18 cases— 9	p.c.
50 to 75	c.c. liquid contents,	4 cases— 2	p.c.
75 to 100	c.c. liquid contents,	3 cases— 1½	p.c.
100	c.c. liquid contents,	1 case — ½	p.c.

These facts prove absolutely that no mechanical obstruction to food exit exists.

As regards the statement that extreme atony will cause stagnation, I have analyzed 121 cases of gastroptosis and divided them into three classes, according to whether the atony was slight, moderate, or extreme, and the fasting contents of these cases are shown in the following table

SLIGHT ATONY—38 CASES.

0 to 25 c.c.	36 cases.
25 to 50 c.c.	1 case.
50 to 75 c.c.	1 case.

MODERATE ATONY—44 CASES.

0 to 25 c.c.	38 cases.
25 to 50 c.c.	4 cases.
50 to 75 c.c.	2 cases.

EXTREME ATONY—39 CASES.

0 to 25 c.c.	37 cases.
25 to 50 c.c.	2 cases.
50 c.c.	no cases.

I think it will be evident as the result of these figures that stagnation in a gastroptosis stomach does not exist.

"Test breakfast in one hour showed 130 c.c., separating into two layers—an upper one-third of clear fluid, a lower two-thirds in depth of well-digested food remains. Slight admixture of gastric mucus; total acidity, 62; free hydrochloric, 28."—On withdrawal of the test breakfast, a certain degree of ali-

mentary hypersecretion is usual. That is, on standing, the test breakfast divides into two portions, a clear, supernatant liquid, and a layer beneath of digested foodstuffs. The ratio between the liquid portion and the lower food portion is between one to one, and one to three. It is a rare exception not to find the test breakfast thoroughly and perfectly digested, and this is due to the preservation of normal gastric acidity and good peptic power.

In 233 consecutive cases achylia was present in 9½ per cent.; subacidity, 8 per cent.; normal acidity, 55 per cent.; hyperacidity, 27 per cent.; so that in 82½ per cent. gastric secretions are normal or hyperpeptic.

The amount of gastric catarrh is trifling, and is usually evinced by the presence of small amounts of gastric mucus. It is well that this is the rule, because these stomachs, by reason of their atony, are better left unwashed.

"The right kidney is one-third palpable."—I wish I had kept account of these patients with gastroptosis who have been diagnosed only as "floating kidney," and advised to have the kidney sutured; certainly 50 must have been given this advice. I do not remember, however, a single case in which, in my judgment, the proposed procedure was not only injudicious, but unnecessary. I do not wish to enter here into the discussion of the pathological significance of a palpable right kidney, or the proper means for its treatment, further than to state my own convictions on the subject: (1) All patients with gastroptosis have a perfect right to have a kidney from one-third to one-half palpable. (2) Such a degree of motility is not productive of clinical symptoms, except in the rarest instances. (3) The diagnosis of floating kidney is not sufficient; the displacement of the other abdominal organs must also be determined. (4) With a palpable kidney and with gastroptosis medical treatment alone is indicated, and surgical treatment absolutely contraindicated, unless in the rare cases in which the Dietl's crisis occur.

Treatment.—The treatment resolves itself into treatment before the atony, in the stage of temporary atony, and in the stage of permanent atony.

In the stage before the atony we have this undernourished patient with sharp costal angles and without gastric symptoms. Such a condition existed in our patient before her fifteenth year. I must again allude to these cases and emphasize the importance of treating children with the enteroptotic habit different from other children. Their physical condition must be built up by out-door life and freedom from exacting school hours. The amount of liquid that they take must be restricted, especially with the meals. Older patients require vacations from time to time, whenever tired by the duties of life.

The second stage, marked by a temporary atony, indicates a continuance of the prophylactic treatment just alluded to. Each patient must learn her limitations; must know exactly how far she can go without being physically or mentally over-fatigued, and keep within these bounds. The most careful attention should be paid to the daily habits of life; to the limitations of water with the meals, and they must be kept over-nourished. In some of the patients a supporting belt is desirable.

The most interesting treatment is that of the permanent stage of atony, and it is in this stage that we see the majority of our patients for the first time. I have not practically abandoned the idea of doing the patients good as long as they keep on their feet. You may try a variety of ways to build them up, you may improve them for the time being; but sooner or later comes a relapse, and after weeks and months of work you find yourself exactly where you started; and I am so convinced of the truth of this statement that I will not take the responsibility of treating a gastroptosis case unless I can put that patient in bed for four weeks. The patient must be put in bed and under the care of an intelligent, tactful, sympathetic nurse. The family, friends, and mail ought to be excluded. The day is arranged on about the following schedule:

Rest Cure.

7:45 A. M.—Tidy, wash hands and face, then teeth, change umschlag.
8:15 A. M.—Breakfast.
8:30-9:00 A. M.—Rest.
9:30 A. M.—Massage (stroking).
9:45 A. M.—Irrigation.
10:45 A. M.—Warm bath, spinal douche, make bed.
11:30 A. M.—Kumyss, crackers.
11:45 A. M.—Rest.
1:00 P. M.—Lunch.
2:00 P. M.—Rest (alone).
4:00 P. M.—Abdominal massage (stroking, and circling, and electricity).
4:30 P. M.—Sandwich, etc.
6:00 P. M.—Drip sheet (alcohol rub).
7:00 P. M.—Dinner.
8:15 P. M.—Massage (general).
9:15 P. M.—Wash hands, make bed.
9:30 P. M.—Kumyss, crackers, clean teeth.
9:45 P. M.—Lights out.

The more strict the seclusion the better the result. Please remember this, and do not be cajoled into the error of admitting over-sympathetic mothers and indiscreet friends into the sick room.

The hot bath and spinal douche consists in immersion (temperature, 105°) for five minutes, followed by a cold spinal douche, 10 seconds. The hot applications must be moist, and may be applied either by hot flannels, spongiopiline, or a moist flannel covered with an electric pad. The whole application to be tightly applied by an abdominal binder; such applications to be changed every two hours in the day and once in the night.

The diet is conducted on about these lines. *For breakfast*—Cocoa; cereal, with cream and sugar; minced meat on toast, or soft boiled eggs; roll, butter, marmalade. *11 o'clock*—Russell's emulsion. *1 o'clock*—Fish or chicken, or bird; two vegetables; a farinaceous dessert (cornstarch, farina, or rice pudding). *4 o'clock*—Either the remains of the farinaceous pudding, or junket, or malted milk. *7 o'clock*—Like the meal of 1 o'clock. *9 o'clock*—The meal like the 4 o'clock.

Throughout the day cream (16 per cent. to one pint) is to be given; and I am not afraid of giving these patients two or three caramels after each meal, as I think it helps the bowels. Liquids at meals are to be restricted. No fruit or red meats are to be allowed.

If the bowels are constipated, the nurse is directed to massage the descending colon ten minutes three times a day, and to use intestinal irrigations by a to-and-fro current, not introducing more than a pint at a time, just as one would wash the stomach. The custom of giving two or three quarts of water at a time is to be deplored.

As regards medicine, it is best to start with small

doses of bromide, a drug indispensable in the treatment of these cases. I frequently employ the following prescription:

℞ Chloral hydrat..... 5i
Sod. bromid..... 5iiss
Aq. chloroform..... ʒiv
Spts. anisi..... qtt. vi

M. Sig.: Teaspoonful in water after meals, three times a day.

and I can thoroughly endorse its use, for you cannot get along without it. After the first ten days substitute for this prescription tincture of physostigma in 10 or 15 minim doses, substituting it for the bromide solution, first after breakfast and then in a few days after supper, so that the patient takes physostigma after breakfast and supper, the bromide after the midday meal and at night. Toward the close of four weeks, three doses of physostigma are given, and but one dose of the bromide, this at night.

During this treatment the patients rapidly improve. The weight increases, the average gain being ten to twelve pounds in the four weeks, and the lower curvature of the stomach rises, so that at the end of the four weeks it lies just under the navel This rise of the lower curvature is no idle fancy; it is to be regularly expected. During the four weeks intragastric faradization may be employed; but I must say I am using it less than formerly, and find that the majority of patients do just about as well without it as with it. In impressionable patients, however, it has a very decided mental effect. The return to ordinary daily life must be gradual, and a week at least should be taken for what I call the hardening process.

The month after the rest cure patients must be careful about overdoing, must lie down every day after lunch, and must wear an abdominal belt. Food between meals must be continued, liquids at meals interdicted, and no raw fruit allowed.

In nearly every case, the first week after the rest cure shows a decided slump in the patient's condition, the patients losing a little in weight and complaining again of their gas and distress. These symptoms will pass in a few days, but it is well to warn your patients in advance that such a slump will probably occur.

Under this treatment it is rare to be disappointed. The patients gain in nutrition steadily for weeks or months. They gain on an average ten pounds in the rest cure, but at the end of the year they are often thirty pounds heavier, and somehow or other the stomach stays up in place. Thes results are so good from such simple means that any operation on these stomachs in the way of stretching them up in place is, to my mind, totally and absolutely out of the question, and should be considered a surgical disgrace.

18 East Fifty-second Street.

Intestinal Ulcers.—In the typhoid ulcer (1) the main axis of the ulcer lies parallel with that of the intestine; (2) it lies opposite to the mesenteric attachment; (3) it has smooth floor and undermined edges; (4) it commonly leads to perforation. In tuberculous ulcer (1) the long axis of the ulcer lies at right angles to that of the intestine; (2) it is not necessarily situated opposite the mesenteric attachment; (3) its floor is not smooth nor are its edges undermined, but rather funnel-shaped and irregular; (4) it is not apt to perforate, but it does not tend to heal, rather to spread.

ON RECENT INVESTIGATIONS OF THE ACTION OF RADIUM ON PLANTS AND ANIMALS.*

By Louis Hussakof, Ph.D.,
New York.

(From the Laboratory of Biological Chemistry of Columbia University, at the College of Physicians and Surgeons, New York.)

Since the discovery of radium a few years ago numerous investigations have been conducted to ascertain the value of this element in medicine and general biology. The results of many of these have already appeared, some containing discoveries of high value for physiology, pathology, or biology, and all indicating that with further study facts of still greater importance may be expected. These papers, however, are scattered through a wide range of journals, some of which are only of local interest and not readily accessible to the majority of investigators. It seemed advisable, therefore, to bring together in a single article a résumé of the leading results thus far obtained. This would present a sort of stock-taking of what has already been done in the various fields, and perhaps, too, help to show the directions in which further investigation is needed.

In arranging my data I found the body of facts so large, that it was impracticable to attempt a résumé of researches in chronological sequence. It appeared more advisable to collect the results obtained in the different fields of research under separate heads. What follows, therefore, is presented in the following sections: (1) Earliest observations. (2) Action on bacteria. (3) Action on protozoa and other microorganisms. (4) Action on tissues. (5) Pathological significance. (6) Action on development and regeneration. (7) Action on plant growth and development. (8) Action on certain specific animal organs or substances. (9) Theoretical considerations and general conclusions. (10) Bibliography.

1. *Earliest Observations.*—The earliest observations bearing on the physiological action of radium rays were made quite accidentally. Experimenters with radium soon observed that it affected the skin of the hands, producing "burns" similar to those resulting from the action of Röntgen rays. Walkoff[45]† and Giesel[21] were the first to record such observations (1900). Giesel carried a preparation of radium bromide in a capsule on his arm for two hours. At the end of that time he observed a slight reddening where the radium container had been applied. After a latent period of two or three weeks the reddening became intensified, local inflammation followed, and the skin came off over the affected area.

During the following year Becquerel and Curie[4] repeated these experiments. They used more active preparations, applied for longer periods, and confirmed the results of Giesel. They, too, observed a reddening at the end of the period of exposure, accompanied by no marked symptoms for several days. At the end of that time, however, the reddening became intensified, and the remaining symptoms described by Giesel were exhibited, *i. e.* inflammation confined to the spot where the radium had been applied, followed by gradual falling off of the skin.

*The fourth paper pertaining to a series of investigations now in progress. See Gies and collaborators, Proc. of the Soc. for Exp. Biol. and Med., II., p. 86, 1905; also *Science*, XXI., p. 988, 1905; *Amer. Med.*, IX., p. 1029, 1905, and *Medical News*, XLII., p. 520, 1905. This paper was prepared at Dr. Gies's suggestion.

†These numbers refer to the bibliography at the end of this article.

They, moreover, established the first principle of the physiological action of radium: "La durée de l'évolution des altérations varie avec l'intensité des rayons actifs et avec la durée de l'action excitatrice (p. 1290).

These experiments drew attention to the physiological possibilities of radium, and led to experiments with it on very diverse types of biological phenomena. Among the earliest were those on the effect of radium on microorganisms.

2. *Action of Radium on Bacteria.*—The first observations were made by Strebel[43] in 1901. He performed only a single experiment, which seemed to indicate that radium rays exercise an injurious effect on bacterial growth. At about the same time a carefully planned and admirably executed series of experiments were being conducted by Aschkinass and Caspari.[3] They worked on *Bact. prodigiosus*, using 1 gm. of a radium-barium-bromide compound. By a series of control experiments they showed that the effects observed must be attributed to the radium rays and not to the other elements of the compound employed. Some of their cultures were protected in places from the effects of the rays by delicate copper wire stretched across. In all such cases the protected portions of the culture, not having been reached by the radium waves, developed, whereas the unprotected portions were arrested in growth, giving, in several instances, singularly clear visual demonstrations of the injurious action of radium rays on bacteria. The authors summarized their observations as follows: "Durch die Gesammtheit unsere Versuche dürfte der bakterienschädigende Einfluss der Becquerel-Strahlen zweiter Art (beta-rays) mit Sicherheit nachgewiesen sein." The minimum period of action that produced a result was one hour. On transferring an arrested culture to normal conditions, it very gradually regained its vitality and began to develop.

In 1904 Alan B. Green[22] found that the radiation from 10 mg. of radium-bromide killed various types of bacilli: *Bacterium coli communis* and *Spirillum choleræ asiaticæ*, after about six hours' exposure. Spore-bearing bacilli required a longer time—from 48 to 72 hours. Vaccine virus was rendered ineffective. Green established also several general principles: (1) The physiological action of radium is proportionate to the distance of the bacterial culture from the radium; (2) Microorganisms killed by exposure to radium rays, after several days, become self radioactive. Rays emanating from such organisms penetrate a thin layer of lead, thus proving to be beta-rays.

Similar effects were observed by E. S. London,[28] working on typhoid and other kinds of bacteria.

Up to that time experiments on bacteria had been carried out with the aim of ascertaining the action of the radium *rays*. During 1905 three German investigators (Dorn, Baumann, and Valentiner[14]) jointly carried out a series of experiments to ascertain the effect produced on bacterial cultures by the *emanation*. The emanation from a relatively large quantity of a "pure" radium-bromide compound (30 mg.) was blown over the mouth of a glass vessel containing various bacterial cultures. In some of their experiments the cultures were grown on gelatin, in others on bouillon. They noted an arrest of growth, and finally the killing of the culture. All germs experimented with were killed in about ten days. Typhoid bacilli they found especially sensitive. They also experimented with radium *rays*. Their data in this connection confirmed the results of previous investigators, and demonstrated that the radiation from 5 mg. of the radium compound killed various bacteria, such as those of cholera and diphtheria.

Quite recently (1906) Bouchard and Balthazard[7] worked with the emanation on color-producing bacteria. They experimented on *B. prodigiosus, B. fluorescens*, and *B. pyocyaneus*, and found that in most cases the color-producing activity was inhibited. In the presence of considerable emanation the germs were killed. In several instances where the radium emanation employed was not intense enough to kill the bacteria, it nevertheless arrested growth.

3. *Action of Radium on Protozoa.*—Among the earliest observations under this head may be mentioned those of Willcock[46] (1904) and of Venenziani[44] (1904). The former found that after several hours of exposure to the radium rays, *Actinosphærium* was killed. Venenziani selected as his subject *Opalina ranarum*. This is a ciliate living in the intestinal fluid of the frog. Because of its transparency, it is a good object for experiment. The organisms were transferred from the intestinal fluid to a watch glass containing a 5 per cent. NaCl solution. Into one such watch glass a fine tube, containing 0.1 gm. of a 10,000 radioactive preparation, was placed; a similar empty tube was used as a control. He performed ten experiments in all. These showed that radium rays first act as a stimulant, since the organisms subjected to the influence of radium survived for about two days, whereas those in the control experiment became encysted and died much sooner. When water, instead of the NaCl solution, was used as a medium the result was even more striking; the organisms not affected by radium dying within ten to twenty hours, whereas those under the influence of the radium rays survived much longer.

Salmonsen and Dreyer showed (1904)[39] that *Nassula* and also *Trypanosoma brucei* are killed by the action of radium rays, the latter in from two to three hours. Cyst-forming *Amœbæ* were affected and in some instances killed. In ciliata they noted a distention of the vacuoles, accompanied by an extreme prolongation of the period of contraction.

But by far the most comprehensive and most conclusive experiments on the effect of radium on protozoa were those performed by Dr. Margarete Zuelzer in 1905.[47] She worked on *Pelomyxa palustris, Amœbæ limax, Arcella vulgaris, Difflugia pyriformis, Actinosphærium, Spirostomum, Lionotus* and *Paramœcium*. It is, of course, outside the bounds of this paper to enter into the details of the individual reactions of these organisms. Dr. Zuelzer's results may here be but briefly summarized. The observations were carried on with the different species for periods varying from a few hours to three or four days. In all cases continued exposure to radium rays led to death—*Pelomyxa* in one to four hours, sometimes only ten minutes; *Amœbæ* three to four hours. The shelled organisms (*Arcella, Difflugia*) showed themselves more resistant—they withdrew their pseudopodia after some ten minutes' exposure to the rays and dropped to the bottom of the vessel. After remaining exposed to the rays for three days in this condition, they were removed from the radium rays and placed in a new culture, and entirely recovered within two hours. In the case of *Spirostomum* it was shown that large individuals, if placed under radium rays, did not divide unless their nuclei had previously divided. In general, Zuelzer's results may be summarized by saying that radium rays act first as a stimulant; this is especially well shown in the case of *Pelomyxa;* secondly, the protoplasm be-

comes progressively more vacuolated, division is arrested, and continued exposure leads to death. *Paramœcium bursaria*, which is green, is not affected as readily as *P. caudatum*, thus confirming Willcock's (1904) observations that chlorophyl-bearing organisms, *e.g. Hydra viridis* and *Euglena*, are more resistant to radium than organisms devoid of chlorophyl.

Before the observations of Zuelzer were published the present writer,[24] at the suggestion of Professor William J. Gies, attempted to carry out a series of similar experiments on the action of radium rays* of various strengths on microorganisms, especially *Amœba proteus*. My experiments were not carried out over sufficiently long periods to lead to any positive results. They are mentioned here only as confirmatory of the observations of Dr. Zuelzer, that the effects of radium rays are not immediate, for during periods of observation of from one to two hours the writer observed no effect on either *Amœba* or *Paramœcium*.

4. *Action of Radium on Animal Tissue.*—Reference has already been made to the observations of Giesel, and of Becquerel and Curie, on the action of radium rays on the human skin. In 1903, and again in 1904, an extensive series of careful experiments were carried out by Danysz[11,12] to ascertain the action of radium rays on various kinds of tissues. He employed chiefly guinea-pigs and rabbits. A chloride compound of radium, having a radioactivity of 500,000, was used. On applying to the skin of rabbits or guinea-pigs for twenty-four hours both the epidermis and the derma were completely destroyed, the connective tissue showing through the wound. On further application of the same radium tube to the wound, for an equal or longer period, no deeper wound resulted. The surrounding connective and muscle tissues were but little affected. This goes to prove that not all tissues are equally susceptible to the action of radium rays. Danysz found, furthermore, that intestinal and serum membranes are less sensitive than the epidermis and derma. The central nervous system, on the other hand, is "infinitely more sensitive than the epidermis." In his 1904 paper he showed also that the degree of purity of the preparation affects the result. He found that the tissues of young animals are more susceptible than those of old individuals.

The results obtained by Danysz are of the highest importance. They have established an important general conclusion, namely, that radium rays do not act with equal effect on all tissues. Epidermis and nerve tissues are particularly sensitive; whereas the subcutaneous tissues (muscle, serous layer, etc.), and the internal organs, are not readily affected. The tissues of young individuals are more easily affected than those of older individuals. Danysz arrived at several other important conclusions, which will be referred to respectively under the heads of pathology and development.

As to physical changes produced in the tissues by radium rays (Exner 1903)[18] has shown that tissues of diverse kinds become phosphorescent, *e.g.* blood, muscle fiber, hair, nails, etc. The lens of the eye produced the most marked luminosity but muscle fiber very little. These observations were confirmed by Bouchard, Curie, and Balthazard (1904). They accord in a general way with the results of the distribution of radium to the tissues after its introduction, as demonstrated in his laboratory, under Dr. Gies's guidance, by G. M. Meyer (1906).[30,31]

*The radium preparations employed were presented to Dr. Gies by Mr. Hugo Lieber.

5. *Pathological Significance.*—From the facts just discussed, as well as from those stated previously, it will be seen that radium *rays* exercise a baleful influence upon animal tissues, more marked in some cases (nerve, epidermis) than in others (muscle). The "burns" resulting to the human skin from a prolonged application of radium are difficult to heal. Remarkable effects of the action of radium on the nervous system were observed by Danysz in 1903. He slipped a glass tube of 1.5 mm. diameter and containing about 1 cg. of a very active salt of radium, beneath the skin of a mouse one month old, so that the tube lay exactly above the cephalic terminus of the spinal column. Within three hours it produced paresis and ataxia. After seven or eight hours the mouse was seized with tetanic convulsions, which, if the tube was left in place, became more and more frequent, finally killing the animal in from 12 to 18 hours. Control experiments with empty glass tubes of the same diameter produced no appreciable effect. Mice from 3 to 4 months old experimented on in the same way died in 3 to 4 days, and mice about a year old died in 6 to 10 days.

Similar experiments were carried out on guinea-pigs and produced substantially the same results. A marked rigidity of the extremities such as occurs in tetanic poisoning was noted, death resulting in from 6 to 8 days.

Very diverse kinds of organisms are killed upon continued exposure to radium rays. Bacteria, protozoa, hydra (Willcock), larvæ of insects, notably the caterpillars of a butterfly, *Ephertia kuehniella* (Danysz), mice, and guinea pigs (Bouchard, Curie, and Balthazard, Danysz), and rabbits (Danysz).

A. Beck[3] has demonstrated (1905) that radium rays deaden the sensibility of the peripheral nerves. In eight out of thirteen rabbits experimented on, sensibility entirely disappeared; in the other five it was only decreased.

The *emanation* from radium also produces pathological effects. Suckling mice were exposed for several days to the emanation from radium, and a few days later developed hyperemia of the lungs (Bouchard, Curie, and Balthazard,[38] 1904). Similar results with emanation were obtained by Dorn and Wallstabe.[16] They found that tap water which had absorbed emanation, when given to rabbits produced no effect. But air containing emanation acted as a poison. Rabbits were kept in such air for one and one-half weeks and showed no effect, but after a latent period of two weeks died suddenly. Their lungs were found to be hyperemic.

The bactericidal action of both the rays and the emanation bids fair to be some day of great service to the pathologist. As was stated in preceding pages, germs of such diseases as typhoid fever, Asiatic cholera, and diphtheria are killed on exposure to radium rays, the time of action varying from a few hours to several days, depending on the purity and quantity of the radium compound employed. The action of rays and of emanation in killing protozoa may also be brought eventually into practical application. There is even hope that knowledge of the action of radium on tissues and pathogenic organisms may be brought to bear on the question of cancerous growths. In this connection might be mentioned the discovery (1905) of Neuberg, that radium affects the fermentative process in cancer cells.

In regard to metabolism, a series of careful experiments have been carried on by Berg and Welker[5] in this laboratory, under Dr. Gies' guidance.

They found that "radium preparations of low activity (240, 1,000, 10,000) containing barium bromide in preponderating proportions were without special influence on metabolism when administered per os or subcutaneously in relatively large quantities. Equal or larger doses of pure barium bromide also failed to show any decisive metabolic effects before fatal results were inaugurated." (p. 409.)

6. *Action on Development and Regeneration.*—The earliest observations on the action of radium on development were those of Geo. Bohn (1903).[9] He performed experiments on 80 larvæ of *Bufo vulgaris* and of frogs (species not specified). The time of exposure to the radium rays varied from three to six hours. He obtained some remarkable results. After a latent period there was noted a retardation in development, giving rise to pathological monsters, some of which died. In these monsters the integument, especially, was affected, being much wrinkled and contorted.

Similar experiments were conducted the following year on *Ascaris megalocephala* by Perthes.[26] He found a marked retardation in the cleavage stages and in the differentiation processes, resulting in abnormal, deformed larvæ which died if the exposure had continued for some length of time.

A series of careful experiments were carried out on a similar subject by Schaper[10] in 1904. He worked with eggs and embryos of *Rana esculenta*, and found that eggs exposed to the action of radium rays at various stages of segmentation or early embryonic differentiation were retarded in development, and that the embryos were dwarfed and deformed. The dorsal region, especially, seemed to suffer, being frequently notched. On exposing larvæ of 4.5-5.3 mm. for five hours he obtained embryos that were much deformed by blister-like outgrowths over the body. Larvæ of *Rana fusca*, 18-20 mm. long, gave similar results, the long period of exposure (24 hours) killing some of them.

Schaper[10] was the first to try the effects of radium on regeneration, employing for this purpose *Triton* and *Planaria*. After an exposure of eight hours he cut off the tails of four *Triton* larvæ and the left hind extremity of four others (1.7-1.9 mm. larvæ). In about ten days when the normally regenerating control larvæ had almost regenerated these lost parts, the ones that had been exposed to the radium had regenerated only short pointed stumps in place of the left hind extremity, and these were arrested in further development. The tail had regenerated but was very short and malformed in places. One or two of these larvæ died about twelve days after the time of exposure. A series of similar experiments were conducted, the time of exposure being nearly twice as long (seventeen hours) with quite similar results, namely a retardation of the regenerative process.

With *Planaria lugubris* the results were as follows: After exposure for three and one-half hours the organisms were cut across in different planes. In eight days they had regenerated very little, although the controls had almost regained their normal form.

Emanation acting on 15 mm. larvæ of *Rana esculenta* produced effects similar to those caused by the rays. Schaper's summary is worth quoting. He notes "eine ausgesprochene hemmende Wirkung der Radiumstrahlen auf die Zellteilung, auf embryonale Differenzierung und embryonales Wachstum, sowie auf den Prozess der Regeneration, . . . die sich jedoch erst nach Ablauf einer längeren oder kürzeren Latenzperiode zu erkennen giebt" (p. 331). These results prove that radium rays act on development and regeneration similarly to Röntgen rays, as shown for the latter by Gilman and Baetjer (on larvæ and eggs) and by Bardeen and Baetjer (on regeneration).*

7. *Action on Plant Growth and Development.*—Some important positive results have already been obtained by investigators experimenting on plants. Max Körnicke[25] was the first to make observations on the action of radium on sprouting and on growth. His results may be briefly stated as showing that radium rays, like Röntgen rays, exercise a retarding effect on growth. But if the preparation employed is not too active there is noted first an acceleration in growth which is only later superseded by a retardation. His later observations (1905) seem to prove that the effect is mainly on the chromatic substance of the cells varying with the strength of the preparation and the stage of development of the plant. The nutritive portion of the plant was found to be more resistant than other portions. No injury was noted to the cytoplasm of the cells. (Roots of *Vicia faba, Pisum sativum,* and bulbs of *Lilium martagon.*) In a series of experiments which aimed to ascertain the difference in action on roots and sprouts, he found that subjecting seeds, either dry or sprouting, to radium for three days, produced a far greater growth in the sprout than in the root before the arrest of growth in both. This indicates, according to Körnicke, an action on metabolism somewhat similar to that of the ultraviolet rays, namely, the radium rays produced a withdrawal of oxygen. Hence those portions of the plant that contain chlorophyll and thus can make good their loss of O more readily than the portions devoid of chlorophyll (roots), are more resistant to radium-action. It will be recalled that the observations of Willcock (on *Hydra viridis* and *Euglena*) and of Zuelzer, demonstrated that this rule holds good also in the case of animals. The combined evidence of both these facts in favor of the view that radium action affects O metabolism is of great importance in the formulation of a theory of the physiological action of radium.

Other experiments of the same character have been made at Dr. Gies' suggestion by Dr. C. Stuart Gager[19] at the New York Botanical Garden. His early results were summarized as follows: "The early stages of seed germination are accelerated if stimulation ranges between the minimum and optimum points [depending upon the proximity of the radium to the plant, the strength, quantity, and condition of the radium salt, the time of exposure, and the nature and condition of the tissue]; otherwise they are retarded. Seeds are less sensitive to the rays when dry than when soaked. When seeds are stimulated during germination, subsequent growth is retarded; but radium rays acting through soil in which plants are growing accelerate both germination and subsequent growth of the shoot. The growth of plants is retarded in an atmosphere of decaying radium emanations." Gager's experiments are in progress.

In connection with the influence of radium rays on the development of the lower plants the work of J. Dauphin (1904)[13] is important. He experimented on *Mortierella, Mucor, Piptocephalis* and *Thamnidium*, and found that radium rays arrest the growth of mycelia and hinder the germination of spores. Cyst-like bodies are produced in the mycelia, which seem to be defensive organs capable of withstanding the radium effect. Spores and mycelia that have

*Bardeen and Baetjer: *Journal of Experimental Zoology*, 2, 1904, pp. 101-05. See also Ibid., 4, 1907, pp. 1-44.

been arrested in development are not killed, but only reduced to a quiescent condition; for on being transferred from under the radium rays to normal conditions, they germinate, and some even develop.

It has also been found that radium rays affect the tropisms of plants. Molisch found (1905)[33] that a zinc compound of radium at a distance of 2 or 3 cm. from the growing plant affects its heliotropism, resulting in distortions. Körnicke (1905) also found that seedlings from seeds which have been exposed to the action of radium lose their heliotropic and geotropic properties. The plants become what Körnicke terms "Radiumstarre." Michaels and De Heen (1905)[32] found that radium rays affect the respiratory processes in plants; less CO_2 is absorbed by sprouting seeds under the action of radium rays than normally.

8. *Action on Certain Specific Animal Organs or Substances.*—From the experiments carried out up to the present time it would appear that radium produces marked effects on various kinds of organs or their biochemical products. M. Mendelssohn[29] found (1905) that on subjecting the electric ray (*Torpedo marmorata*) to the action of radium rays a remarkable effect followed. After a latent period of several days the fish lost its power of giving electric discharges, but the electric power returned within a few days. A complete destruction of the electric reaction was not observed. Incidentally it was noted that following the exposure to radium the spotted skin of *Torpedo* undergoes a series of color changes, becoming first more uniform, then red, brown, and lastly yellow. And after some time the skin peels off.

Radium rays also have a pronounced effect upon various biochemical substances. Henri and Mayer[23] studied the action of the rays on several ferments and on red corpuscles. They found that invertin, emulsin, and trypsin, when subjected to radium radiation, progressively lose their activity, and after several days of exposure become completely inactive. Oxyhemoglobin of the dog and the frog is transformed into methemoglobin and slowly precipitated. Carbonated oxyhemoglobin remains intact. Red blood corpuscles under the action of radium rays give up hemoglobin and salts into the solution in which they are suspended and which under normal conditions preserves corpuscles intact (hemolysis).

Schmidt-Nielson[41] has observed (1904) that radium rays destroy the activity of chymosin; but he believes the result to be due not to the radium rays but to the ultraviolet rays caused by the phosphorus employed in his experiments.

An interesting study in this connection is that of Phisalix (1904)[37] on the influence of radium rays on the toxicity of the venom of the viper. He dissolved the contents of the poison sac of a viper in chloroform in the proportion of 1 to 1,000. He then took four equal portions of this solution, set one aside and exposed the other three to the action of radium rays for different lengths of time: one for six hours, another for twenty hours, the third for fifty-eight hours. These solutions on being injected into four guinea-pigs gave a clear demonstration of the progressive action of the radium rays on the toxicity of the venom. Thus the non-radiated portion caused death within ten hours; the part exposed to radium for six hours caused death in about twelve hours; and the solution exposed for twenty hours produced fatal results in about twenty hours; while that exposed for fifty-eight hours produced no toxic effect whatever. In all cases except the last the symptoms were the same in kind. In the last-mentioned experiment there was neither local nor general effect observable. Hence the radium rays gradually modify, and finally even destroy, the activity of the venom of the viper.

9. *Theoretical Considerations.*—As is now well known, radium emits three kinds of rays which have been designated respectively, the alpha, beta, and gamma rays. The alpha rays have the least penetrative power, being absorbed by a plate of lead only a few centimeters thick; the beta rays are deflected by an electromagnet. The attention of physiological experimenters was early attracted to the question as to which kind, or kinds, of radium rays caused the physiological effects. By an ingenious experiment A. Exner[17] in 1904 gave a very decisive answer to this question. He fixed two white mice in such positions that the rays issuing from the radium container passed over the field of a ring-shaped electromagnet disposed in such a position relative to the two mice that the beta rays were deflected upon a point on the outstretched tail of the one, while the gamma rays impinged on a corresponding spot on the tail of the other. The distance of each affected spot from the radium source was about 3 cm., so that the alpha rays practically did not enter into the result obtained. After an exposure of eighteen hours and forty minutes the mice recovered quickly, but after a latent period of fifteen days an ulceration appeared on the tails at the places corresponding to the points exposed. Hence both the gamma and the beta rays must be regarded as physiologically active. Both rays produced approximately similar changes in the skin. But the deflected rays (beta) produced somewhat less effect than the gamma rays. The experiment was repeated and gave a similar result the second time.

More recently Dr. C. Stuart Gager at the New York Botanical Garden (1905-06) has confirmed these results, showing that in the case of plants "the effect is the same in kind, whether the plants are stimulated with gamma rays only, or with alpha and beta rays as well. When three kinds of rays are employed the effect, within the same time, seems to be increased."

The next question that may be considered is the manner of action of the rays. Is the change produced in living tissues by either the rays or the emanation a *physical* or a *chemical* one?

From the present status of our knowledge, it would certainly appear that the action is a chemical one. This was suggested by some of the earliest investigators with radium, *e.g.* Giesel, Schwarz. They reasoned that the latent period which followed after exposure and before any result was manifested, signified a molecular rearrangement and hence meant a chemical change.

To examine this problem more closely, Schwarz[42] performed some experiments on hens' eggs (1903) which so largely contain the cell constituents. He found that radium rays affect the various egg constituents very differently. The greatest effect is produced in the yolk, which is decomposed, whereas the ovalbumin except for being somewhat thicker, is not affected at all. He argued that the radium rays decomposed the lecithin in the yolk, and therefore drew the conclusion that the action of the radium rays on all tissues was due to the same cause, namely, the decomposition of lecithin. He found apparent confirmation for this view in the fact that cells which are rich in lecithin, such as those of the regenerating layer of the epidermis, of the nervous system, and of growing tumors, are most markedly affected.

But in the few years now elapsed since this theory was put forward, results have been obtained which throw doubt upon this explanation. Neuberg has

shown that radium rays can decompose neither pure lecithin nor proteins and that therefore they probably do not decompose the lecithin within the cell.

In some way still not understood oxygen seems to play a rôle in the process involved; for, as demonstrated by Willcock, Zuelzer, and Körnicke, animals and plants which contain chlorophyl and can therefore produce oxygen readily, are more resistant to the action of radium rays than those devoid of it. This is very strikingly shown in genera which have both chlorophyl-containing and non-chlorophyl-containing species such as *Hydra viridis* (Willcock) and *Paramœcium bursaria* (Zuelzer); also in sprouts as compared with roots (Körnicke).

On the whole, it cannot be said that we yet have sufficient experimental data for a solution of the problems involved in the action of radium. While suggestive working hypotheses may be thrown out by one or another investigator, the fact remains that more data are needed before we can arrive at a logical explanation of the general and local action of radium rays or emanation upon organisms.

Differential Diagnosis of Croup.—True croup is either laryngeal diphtheria or a streptococcus infection. In either case there is a prior stage of malaise, accompanied by chills, fever, and sore throat. The fever may become very high. A membrane forms, in which are found the Klebs-Loeffler bacillus or streptococci. Spasmodic croup generally comes on suddenly, at night. There is no appreciable fever, no previous malaise or sickness, and often the patient is asleep again by the time the physician arrives. There is frequently a thick, tenacious mucus, but neither Klebs-Loeffler bacilli nor streptococci are present. It is entirely a local disturbance.

SULPHUR WATERS IN THE TREATMENT OF SYPHILIS.

By J. DARDEL, M.D. (Paris),

AIX-LES-BAINS, FRANCE.

THERE are three indications in the treatment of syphilis: (1) Treatment of the disease itself. (2) Prevention of its return. (3) Attention to the general state of health. Treatment with mercury and iodide answers to the first two indications, but not to the last.

The treatment of syphilis, in order to be thorough and complete, should consist not only in the administration of mercury and iodide, but also in the use of certain means to help the reaction of the organism and to enable it to stand the treatment without danger or inconvenience. In a word, whereas mercury acts against the syphilitic virus, an auxiliary treatment is necessary to combat the general decline of health. As Fournier has said, "attend to the general state no less than to the disease itself, and when you are called upon to treat a case of syphilis do not concentrate all your attention on the disease alone." One should never forget that besides the germ it is necessary to consider the soil upon which it develops. A given seed will grow better in a well prepared and favorable soil. In the present case a favorable soil for the growth and development of the syphilitic virus is a weakened and debilitated system, one which is capable of offering the slightest resistance. Therefore, after treating the disease itself it is necessary to attend to the patient from a more general point of view, using all other therapeutic means, such as hygiene, etc. It is hardly necessary to insist further on the importance of attending to the general state in syphilis. As Guéneau de Mussy has said, "syphilis is a soil upon which all kinds of mould will grow and prosper. From the very beginning of the infection nutrition is markedly affected, the entire organism is diseased and weakened. The anemia and asthenia of syphilitics are well known to all."

If mercury is able, on the one hand, to combat the specific lesions and symptoms, it cannot, on the other, act against the lowered state of the nutrition. Besides, mercurial saturation is sometimes obtained too rapidly, and the organism can often scarcely stand the dose necessary to obtain the therapeutic action; one must therefore help the organism to tolerate the treatment. We see, then, that the general treatment has two objects in view, viz., (1) to strengthen the patient, and (2) to help him to stand the exhibition of high doses of mercury without danger.

We shall consider here only the sulphur cure in the treatment of syphilis. It may be stated, however, that the hygienic treatment rests upon other factors, *e.g.* a thorough knowledge of the patient's constitution, which is a great help in carrying out the treatment; the avoidance of all excess, particularly alcoholic; hydrotherapy; administration of tonics, such as iron and arsenic.

Treatment by means of mineral waters, which is one of the oldest adjuvant means employed with mercurial treatment, was at first based simply on empiricism, but is now better known and is applied scientifically. In certain cases it is directed against the anemia or cachexia due to the syphilitic poison. In others it is applied against certain organic defects which existed before the onset of syphilis and which complicate the latter (scrofula, arthritism, neuropathy). Lastly, thermal cures increase in a marked fashion the tolerance of the organism to mercury.

Three categories of mineral water stations are suited for the treatment of syphilis: the *saline*, the *arsenical*, and, above all, the *sulphurous*. The choice of the spa depends upon the physiological and therapeutic action of the water.

Saline waters have a powerful action on nutrition and increase the phenomena of oxidation. Their most important indication is when syphilis is complicated by the existence of scrofula or of syphilitic cachexia and it is necessary to stimulate the whole organism.

Arsenical waters are to be recommended when syphilis affects a torpid nature. They do not really act against syphilis itself, but, according to Mauriac, against certain affections which syphilis gives rise to.

Sulphur waters are those whose therapeutical action is the most marked.

The use of sulphur in the treatment of syphilis dates a long way back and its therapeutic action had not escaped the notice of the earliest physicians, but it was Frascator, in 1545, and Cabias, in 1622, who distinctly advised the use of sulphur waters against venereal disease. We might also quote the names of Fontan, Pegot, Astrié, Lambron, Blanc, and Borden.

At the present time the favorable action of the sulphur treatment in syphilis is admitted on all sides. Formerly these waters were given only when the patient had passed the secondary period, for it was feared they might give rise to mucous and cutaneous accidents. They were given also to patients who *seemed* quite cured, in order to know for certain whether they were so or not, for in the latter case symptoms reappeared after a sulphur treatment. This method is now quite abandoned.

The physiological action of the sulphur cure is complex and depends on several factors. One must take into consideration the chemical composition of the water, the quantities it contains of sulphur, sulphides, alkaline silicates, organic matter; also its temperature and its electrical action. To these factors, which appertain to the water itself, one must add the mode of application of the water, the altitude of the locality, and the hygienic circumstances in which the patient is placed.

The general symptoms which appear in the course of syphilis show how deeply the nutrition is affected. Nothing is therefore more logical than to institute a treatment whose principal action is to stimulate all the functions of the economy. Sulphur waters, whatever may be their origin, act by the presence of one or several of the following substances: Sulphur in its natural state, sulphureted hydrogen, sulphides of potassium or sodium. This applies to sulphur introduced into the organism by whatever means of absorption, by the mouth (as a beverage), by the lung (inhalation), or by the skin (baths).

In the organism the sulphur forms alkaline sulphides. The latter, whether they are contained in the mineral water itself or whether they are formed as a secondary product by a combination of the sulphur, behave in an identical manner. They are decomposed and give rise to hydrosulphuric acid, which is introduced into the blood. A certain quantity of them, however, undergo oxidation and form hyposulphites, sulphites, and sulphates, the action of which we will study later on. Sulphureted hydrogen seems to be the final product of all the different preparations with a sulphur basis. It is found

in sulphurous waters and it can thus be absorbed directly by the lungs and by the digestive tract. A great part, however, of the sulphureted hydrogen is produced in the organism from combinations of the sulphurs and the sulphides.

The elimination of the sulphureted hydrogen takes place rapidly through the lungs and the skin. Another portion, less stable, is carried away in the circulation, meets with oxygen there, and is transformed into hyposulphurous acid, sulphurous acid, and sulphuric acid, and finally into sulphate of sodium.

Alkaline carbonates, silica, iron, iodine, and chlorides increase the action of the sulphur, each element giving to the mineral water which contains it special characteristic therapeutic value.

The different ways in which the waters are used may of course be varied as required. Given by the mouth or as douches, baths, inhalation, etc., their indications and effects are very different.

Experience has shown that sulphur waters have a general tonic and exciting action. This stimulant action, however, depends more on the mode of treatment than on the waters themselves, and the "thermal fever" which has been described by certain authors is due to a too energetic and rapidly applied treatment. The cure has a favorable action on all the organs. The appetite is stimulated, the red corpuscles are increased in number, the urine is more abundant, and the quantity of urea eliminated is more considerable. Nutrition, which is retarded by the direct action of syphilis, is stimulated and activated by the use of sulphur waters.

We have considered the general action of the sulphur cure, let us now consider its special action on the absorption and elimination of mercurial compounds introduced into the system. Mercury is not absorbed in its metallic form; whichever may be the pharmaceutical form used, it penetrates into the system in the form of bichloride of mercury or of compounds such as chlorobromides, chloroiodides, chloromercurates. These different changes take place with the help of the alkaline chloride of the blood plasma. Bichloride of mercury forms with albuminoids a white precipitate insoluble in water. On the other hand, an excess of albumin and especially a solution of alkaline chlorides may dissolve afresh this precipitate of albuminate of mercury and set it free in the circulation. Sulphur waters contain certain compounds which are capable of redissolving the mercury albuminates much better than sodium chloride, which is the principal means the organism possesses of introducing the mercury into the circulation. This power of sulphur waters to render mercury (*i.e.* the precipitated albuminate) more soluble increases very greatly the absorption, action, and elimination of the latter.

A given quantity of mercury, instead of remaining in part in the state of insoluble salt, passes entirely into the circulation in the soluble state and its therapeutic action is complete.

The interesting researches of Desmoulières have confirmed those of Astrié, thus proving experimentally a fact which had clinically been shown to be true long before.

"Sulphur waters," says Desmoulières, "may contain not only sulphureted hydrogen and sulphides, but also substances due to the alteration of these, and the alteration is all the more rapid that the water contains more silica. The sulphur of the sulphureted hydrogen and of the sulphides, set free under the influence of the carbonic acid and oxygen, is oxidized little by little and gives rise to hyposulphurous acid, sulphurous acid, and sulphuric acid, or rather to the sodium salts of these acids, sulphate of sodium being the last term of the oxidation."

Let us recall briefly Desmoulières's experiment to show the action of sulphur on mercurial compounds. If one add to 5 c.c. of serum 2 c.c. of a solution of bichloride of mercury an abundant white precipitate is formed. If one then adds 2 c.c. of a 1 per cent. solution of monosulphide of sodium, the precipitate immediately dissolves. Sulphureted hydrogen plays a similar rôle to the monosulphides, the albuminate of mercury precipitate being dissolved by the presence of a small quantity of the gas. Hyposulphite and sulphite of sodium possess the same power, but the sulphate of sodium does not. The action of sulphur waters is therefore all the greater when the sulphur compounds which they contain are more removed from their term of oxidation.

In waters containing chlorides and sulphides the sodium chloride adds its effect to that of the sulphureted hydrogen and sulphides.

We shall now consider the practical therapeutical conclusions which may be drawn from the foregoing.

1. Sulphur waters act on the mercurial compounds stored up in the organism and facilitate their elimination. Long after a mercurial treatment one can find traces of mercury in the organism, especially in the liver, the kidneys, and the lymphatic glands. After the ingestion of sulphur water, mercury has been found in the urine several weeks after the patient had ceased taking the mercury, the urine containing no mercury before the sulphur cure had been instituted. Furthermore, patients who had ceased taking mercury for more than a year have presented symptoms of mercurial intoxication (salivation, stomatitis) when beginning a sulphur cure; these symptoms, however, soon disappeared under the influence of the cure. These facts prove conclusively that the mercury stored up in the economy is set free in the circulation.

2. Sulphur waters allow a very powerful or energetic treatment of syphilis, for they facilitate the absorption of high doses of mercury without fear of intoxication. This is only natural, for sulphur rendering mercury more soluble prevents all accumulation and therefore any accident; at the same time it allows stronger doses to be used and a more rapid and more energetic action to be obtained.

In this connection Werbeck's treatment is often quoted for the success he obtained in treating workmen employed in an ice manufactory and suffering from mercurial tremor. He used to give them a patent medicine, the principal element of which was sulphur.

Sulphur waters are therefore to be prescribed to patients who stand mercury badly, to those who present symptoms of intoxication as soon as the mercurial cure is given for any length of time, also to those whose whole system is saturated with mercury with a possibility of a rather dangerous accumulation of the latter. In conclusion, it is important to help the diffusion of the mercury stored up in the different organs of the body, to assist its elimination, and thus to obtain its full action, by the exhibition of sulphur waters.

Before considering the sulphur cure itself, we must consider an important question. Ought mercury to be administered to a syphilitic before or after the hydrotherapeutic treatment? If the patient has just lately undergone a strong mercurial treatment, it is not necessary to continue the latter during the water cure.

But it is only in a case of this sort that the water cure is given alone, for the good effects of the sulphur medication are especially felt when mercury is given at the same time. It is in proceeding thus that the patient will be able to absorb really high doses of mercury without the slightest danger of any accident.

Which is the best method of administering mercury? We have the choice of three methods to introduce mercury into the system: by the mouth, by inunction, and hypodermicallly. The first method is the one which used to be the most employed, but we do not consider it applicable when undergoing a sulphur cure, for it is slow and uncertain, whereas a rapid and energetic action is required. The old method of giving mercury in the mineral water itself must particularly be avoided, for if mercury is taken less than two hours after the sulphur water it forms in the digestive and circulatory systems an insoluble sulphide and is therefore of no therapeutic use. Inunctions are much preferable; they should be made immediately after a bath. Each inunction which should be made energetically, should last a longer or shorter period of time, according to the dose of mercury employed. After the inunction the region rubbed should be covered with a piece of flannel, which must be left on until the next day. The dose of mercurial ointment to be used varies with each case. It is therefore useless to indicate quantities here. We must, however, draw attention to a fact which proves how much the tolerance of the system to mercury is increased by a sulphur cure. During the cure inunctions may be made every day with doses twice and even three times as great as under ordinary circumstances, without provoking symptoms of intolerance. It is evident, therefore, that one can obtain a much more energetic therapeutic action.

Of all methods we much prefer the hypodermic injections, using soluble salts of mercury.

The injections must be made with great care in order to prevent the formation of nodes, which might, in certain cases, interfere with the treatment. The injection of soluble salts constitutes the real and scientific method of treatment. It has many advantages—cleanliness, convenience, a therapeutic action superior to that of all other methods, no irritation of the digestive organs or of the skin, exact dosage of the mercury, whose absorption and action are rapid, regular, and constant. Lastly, the chances of intoxication are reduced to their minimum. The choice of the salt to be used, the dose of each injection, the number of and the interval between the injections, cannot be stated in a general way. Personally we use either the benzoate or the biniodide of mercury, but other salts may be used with good results. As a matter of fact, it is best to use the salt to which the patient is the most accustomed and with which one has already obtained good results. Each case has its own indications. The physician must proceed with caution, especially at the beginning of the treatment, increase progressively, and carefully watch the state of the patient in directing the treatment. There are many sulphur spas in France and elsewhere. In France among the best known are Luchon, Barèges, Cauteret, Uriage Challes, and Aix les Bains. As it is impossible for us to describe the treatment used at all these different places, we shall choose as a type the cure as it is applied at Aix-les-Bains.

The means used in the treatment differ in form and in importance. We shall describe only those which may be associated with a mercurial cure. The water at Aix is a sulphide calcic water with a temperature of 45° C. It is used externally, the Marlioz water being reserved for internal use. The waters are used in three different ways: (1) The "douche d'Aix"; (2) vapor baths; (3) internally.

The "douche d'Aix" is a combination of a douche or shower bath and massage; it is also called a "douche massage" and constitutes the real specialty of the spa. It is not a shower bath in the ordinary sense of the word, for the water is not used cold or for a short duration of time, neither is it a massage pure and simple. It consists in a kneading, a "pétrissage" of the muscles, and at the same time the body is sprinkled all over with the warm sulphur water. The douche massage is given in rooms some of which are completely closed in, others have openings at the top in order to allow the vapors to escape. In each douche cabin the temperature of the water varies from 14° to 43° C. (57° to 109° F.), and the douches can be given hot, cold, or tepid. The pipes which bring the mineral water and the cold water end in two metallic boxes fixed to the wall. One of these boxes, called "boite de mélange," is open and is fixed at about five feet from the ground. The mixture of the two waters takes place freely, so that the pressure remains always the same. This mixture is used for the back and the upper part of the body. The other box, called "culotte," or "jumelle," is made of copper and is hermetically closed. A single tube starts from the bottom of this box and the hot and cold water mixed in this box is used for the patient's limbs. In the "culotte" the water has a pressure which varies with each story in the building.

The patient sits on a wooden chair 30 centimeters high with his arms on an elbow-rest and his feet on a wooden footstool. One of the doucheurs is in front of the patient, with the tube which brings the water from the closed box, under his arm. As he sprinkles the water over the limbs he rubs and kneads the muscles and in certain cases performs passive movements of the joints. The other doucheur is behind the patient with the tube which brings the water from the open box. He sprinkles the back and shoulders and at the same time massages the muscles of the neck and trunk. During the whole time of the massage the patient is inundated with the mineral water.

After a certain time the patient leaves the chair and lies flat on his chest on an inclined plane or massage table. The doucheur, still holding his tube, massages the muscles of the back, thighs, and legs. In this position the muscles are completely relaxed, and it is therefore very favorable for a thorough massage of the posterior part of the body. The massage of the back may also be performed, the patient sitting on the chair and leaning forward with his hands on the elbow rest. When the massage is finished the patient is placed in one of the corners of the cabin and is given a "douche en pluie" (shower or rain bath), or a "douche en jet" (spouting bath). This latter part of the treatment is of great importance and physicians are able to obtain different results according as they use a round jet or a spread-out jet, a warm douche or a cold one, or, lastly, a Scotch douche. After the douche, the patient is thoroughly dried and wrapped up in a flannel dressing gown and a blanket. He is then carried out in a kind of Sedan-chair and put to bed. Abundant perspiration soon comes on and lasts generally about twenty minutes.

Vapor baths, local or general, may be given in different ways. Certain cabins, opening into the douche rooms, are called "bouillons." In these the water is pulverized and transformed into a vapor

with a temperature of about 40° or 43° C. (104° to 109.4° F.). By the use of the "bouillon" rapid and intense perspiration is induced and the patient breathes the sulphur vapor. An apparatus called "Berthollet" consists of a large box in which the patient sits with only his head out of it, and a mixture of air and sulphur vapor is circulated through the box. If required, the sulphur vapor may be made to act on a limited region of the body only.

The Marlioz Water.—The internal treatment consists in drinking the water of the Marlioz spring, which is the most sulphurous of the three springs which form the hydromineral group of Aix. The Marlioz water is sulphurous, alkaline, and contains iodides. It has a temperature of 14° C. (57.2° F.). It is easily digested and is eminently suitable for an internal sulphur cure. It is also used for certain local applications (throat, nose).

We have insisted quite sufficiently on the general action of sulphur waters. The "douche d'Aix" stimulates the circulation and nutrition, and acts as a splendid tonic. The "bouillons" help elimination through the skin and absorption of sulphur vapor. The vapor baths act locally on the skin.

Indications of the Sulphur Cure.—The question, at what period of the disease a patient will derive most benefit from a sulphur cure, is no longer discussed nowadays, for it is generally admitted that the cure is indicated at any period, since nutrition suffers and a general stimulation of the system is required from the very beginning of the malady. We must not forget, however, that patients suffering from arteriosclerosis, or from liver trouble, or highly nervous people, should not undergo an active sulphur cure.

A sulphur cure is indicated whenever a patient stands mercury badly, or when he can tolerate only a very small and insufficient dose, or, finally, whenever, in spite of the mercurial treatment, a therapeutic action is not obtained.

The cure is also indicated in the serious forms of syphilis, especially in those forms which are severe at the very outset, also when syphilis supervenes in worn out and enfeebled patients, and in the obstinate forms which resist treatment.

Certain particular cases require a rapid and energetic treatment, with injections of large doses of soluble salts, as they are applied at sulphur spas. These are: Lesions of the nervous system, due to syphilis; ulcerative lesions which threaten to destroy an organ or even a whole region; in a word, all cases in which a rapid action is necessary in order to prevent destruction or disorganization of tissue and in which time lost cannot be regained.

In conclusion, a sulphur water treatment has not the pretention of curing syphilis, but it forms the best auxiliary treatment which may be combined with a course of mercury, as it helps very greatly the absorption, action, and elimination of the latter.

The Diagnostic Value of Pain.—George Peacocke speaks of some of the difficulties which one meets in accurately locating the origin of any given pain. Pain is so often a referred pain that, although both pain and tenderness are usually present in the immediate neighborhood of the affected organ, the pain that causes most distress is situated in some more remote part of the body. As the viscera themselves are not sensitive, the pain to which they give rise is indistinguishable in many cases from pain arising in the body wall. The idiosyncrasy of the individual to pain is a difficulty which is present at every turn. The physician is largely dependent upon the patient's own statement that he suffers pain. In the case of infants and young children, the existence of pain is discovered by the recognition of visible signs of suffering only.

EARLY DIAGNOSIS AND HOME TREATMENT OF PULMONARY TUBERCULOSIS.*

By EMMET KEATING, M.D.,

CHICAGO.

CLINICAL ASSISTANT, DEPARTMENT OF MEDICINE, RUSH MEDICAL COLLEGE, PHYSICIAN TO THE SWEDISH BAPTIST HOME FOR THE AGED, MORGAN PARK.

In what I have to say about the early diagnosis of pulmonary tuberculosis, it is not my purpose to consider those patients who have continuous cough, suspicious expectoration, emaciation, and, upon physical examination, easily distinguished evidence of destruction of lung tissue and cavity formation.

I shall discuss that large number of patients who seek advice before the above symptoms have appeared, and who have no suspicion of a tuberculous infection. If these cases can be correctly diagnosed they will, for the most part, promptly and readily respond to proper treatment.

One of the first things impressed upon the student when he begins the study of physical diagnosis is the importance of examining the lungs in all affections. The value of this teaching should not be gainsaid or overlooked by the careful physician, but in beginning pulmonary tuberculosis the lung findings should be considered of minor importance, as evidence for or against the existence of tuberculous infection.

Although it is a well established fact that disease of the lungs gives rise to symptoms that may be indicative of trouble in some other organ, the involvement may be of such small extent as either to escape notice or to be considered not incompatible with the findings in seemingly healthy individuals. For this reason the physician who depends upon an examination of the lungs in making an early diagnosis of pulmonary tuberculosis, will often fail to arrive at a correct conclusion.

Knowing that circumscribed tuberculous areas give rise to changes in the lung tissue which, so far as palpation, percussion, and auscultation are concerned, differ in small degree from inflammatory conditions brought about by many other agencies, it is patent that the chest examination will not present evidence sufficient to distinguish between other beginning active processes and the results of repair that are not inimical to the well being of the affected individual. To avoid error, if the findings show a departure from the normal, too much stress should not be placed upon the examination of the chest, but what it reveals should be considered as confirmatory rather than positive evidence of tuberculosis.

In many morbid conditions histories do not aid greatly in making a correct diagnosis. In pulmonary tuberculosis the history is of the utmost importance. The family history should be carefully taken, and anything pointing to tuberculosis in the parents or brothers and sisters of the patient, noted. In obtaining this as well as the personal history it is not uncommon for the patient to deny or conceal the fact of tuberculosis existing in any of the relatives. The possibility of encountering such evasions makes it necessary to exercise a good deal of skill in questioning, that deception may be detected. Inquiries should also be made regarding the association of the patient with anyone suffering from the disease.

The occupation should be considered; but as these

*Read before the annual meeting of the Second Councilor District of the Ohio State Medical Society, at Springfield, Ohio, April 11, 1907.

patients are recruited from every trade and every profession, the occupation is not so much of a factor except in those cases in which dust and lack of sunlight prevail. The spitting of a small amount of blood may antedate physical signs in the lungs from one to two years.

To learn from what diseases of childhood the patient suffered, it is not sufficient simply to ask if he or she had the diseases of childhood, but it is necessary in the majority of instances, especially in dealing with the ignorant, to specify each disease; such knowledge may be of value from the fact that during and subsequent to such attacks the resistance of the child being lessened, it may readily fall a prey to tuberculous infection, which may remain quiescent until adolescence.

In addition to those disease processes of adult life that are well known to have tuberculosis as a sequel, syphilis is considered a strongly predisposing factor in the development of pulmonary tuberculosis.

In women, the menstrual history is not of a great deal of importance, only as disease of the uterus, tubes, or ovaries might affect the general health of the patient. It is not uncommon for women who are the victims of pulmonary tuberculosis to menstruate regularly until a short time before death.

One thing that has impressed me in these cases is the vagueness of the subjective symptoms. Many of the patients come rather unwillingly, brought by anxious relatives who see that something is wrong. The patients will state that for some days or weeks they have not been feeling well. They become tired easily—especially in the afternoon. Sometimes they will complain of chilly sensations, but rarely state that they have noticed the presence of fever. After a year's treatment tuberculous patients will often come into the office with a mouth temperature of 100° Fahr., who, if asked as to whether or not they have fever, will reply that they have not. Headache may be present.

When the patient complains of pain in the chest it is quite frequently in the region of the heart. The cause of this pain is difficult to explain, as postmortem examination of the heart in cases of death from pulmonary tuberculosis does not reveal anything in either the pericardium or the organ itself that is especially different from conditions that are found when death has resulted from other causes.

Loss of weight is found, but this may be of so small an amount that in itself it would not aid in making a diagnosis. An indefinite history of nightsweats may be obtained. In view of what has been taught regarding pleurisy and pulmonary tuberculosis, the number of early cases that I have examined, complaining of or presenting evidences of pleurisy, is remarkably small.

While gastric symptoms are apt to be pronounced fairly early in the affection, the patient may be entirely free from distress and state that the appetite is good, and that the taking of food causes no discomfort. Constipation exists in about 50 per cent. of cases. Insomnia is often a feature, especially in women, as well as an irritable condition of the nervous system.

Contrary to the belief formerly held that tuberculous patients are happy and hopeful, I find that despondency may be present to a marked extent. A slight degree of despondency may be detected in nearly every case.

Cold, and sometimes clammy condition, of the feet and hands is common. Dilated pupils have been considered of diagnostic value. I have found this condition in a few cases—more often in women than in men, but do not consider it of much significance. The red line of the gums at the margin of the teeth is often seen, and I am inclined to believe is of considerable diagnostic value. Tonsils that are chronically inflamed, and a number of decaying teeth are pointing straws. Freer speaks of the pale larynx and the often present non-tuberculous laryngitis associated with early pulmonary tuberculosis.

Inspection of the chest in very early cases will reveal nothing abnormal. The expansion may be restricted, as these patients are what might be termed shallow breathers. When the disease is a little more advanced, retraction beneath the clavicle of the affected side is at once detected.

The shape of the chest is not of so much significance. Tuberculosis is found in the stocky form of the Jew and in the burly figure of the blacksmith, as well as in the slender and taper thorax of the more delicately built. Progress of the disease, with the accompanying emaciation, will generally account for the so-called "phthisical chest," or "paralytic thorax."

If the first examination of the patient is in the afternoon, a temperature of 99° to 100° Fahr. is often found, with a pulse of 80. A pulse of 80 at the first examination is much more suspicious than that of 100 or over, as the latter rate is more apt to be due to excitement. In considering temperature the elevation due to intestinal fermentation, to chronic appendicitis, the ½ to 1 degree found in subacute attacks of cholangitis, and the slight rises in temperature of anemic origin, must be excluded.

At this time what may we expect to find in the lungs? In some cases the most careful examination will reveal nothing that would warrant us in saying that the infection exists. In other cases, as stated above, we shall be in doubt as to whether we are dealing with a healed lesion or with the result of a simple bronchitis. When the process is sufficiently advanced to present slight physical signs, we may expect to find a slightly higher percussion note just beneath the clavicle. This dullness does not extend below the upper border of the second rib. In the study of slight variations of the percussion note some one has advised that eighteen to twenty blows be struck with the percussion hammer instead of the customary three or four. I have found this a wise proceeding where doubt as to change of note exists. With the stethoscope over this area an inspiratory sound will be heard that is harsh or jerking in character, or both conditions may be present. The expiratory sound will be prolonged and blowing, in distinction from the short, soft murmur of the normal lung.

Râles, either dry or moist, are seldom heard. To elicit râles that are not easily detected the patient should be instructed to breathe deeply. Bronchial breathing is more readily distinguished by having the patient breathe rapidly. Early in the disease the Germans lay stress upon *spitzen katarrh*, a condition in which an occasional click is heard.

Posteriorly, in the lung involved, increased vocal fremitus may be found. The higher percussion note may not extend below the spine of the scapula. The abnormal breath sounds heard beneath the clavicle may be here more pronounced and the whispered voice is plainly transmitted to the bell of the stethoscope. Pectoriloquy may be noted as low as the fourth rib.

In those cases in which an elevation of temperature is not found, the patient should be furnished with a chart for daily recording of pulse and temperature. This record should begin at 8:00 A.M.,

the pulse and temperature being recorded every two hours until midnight. It is not necessary to have a printed form, as a suitable chart can be readily prepared by the physician. In some cases fever may not be found during the day, but will often be present between 10:00 P.M. and midnight. If a week's daily record shows no temperature elevation, then the rectal temperature should be taken. In one of my cases in which the pulse rate was constantly 80, it was three months before a temperature of 99° Fahr. was obtained in the mouth.

The propriety of the use of tuberculin as a diagnostic aid is a question. In 1901 Osler stated that it was harmless. Francine says that he has seen no ill effects from its use at the Phipps Institute. Trudeau, speaking from an experience of fifteen years, states that he has noted ill effects follow its use in three cases; but expresses a doubt as to whether these ill effects were due to the tuberculin or were merely a coincidence. While he concludes by considering it a valuable test, he advises against its use unless a careful application of clinical methods has failed to establish a diagnosis.

When preparing this paper I wrote Dr. Klebs, asking his opinion regarding the diagnostic and therapeutic use of tuberculin by the general practitioner. I quote his letter in full. Dr. Klebs says: "As to the usefulness of tuberculin I have very materially changed my opinion since I expressed myself last about it in 1898 (*Boston Medical and Surgical Journal*). I held then that its value as a therapeutic agent seemed to me very doubtful, the hygienic-dietetic treatment offering much better prospects and with a greater degree of safety. On the other hand, I advocated its use as a diagnostic aid, although needed only in very rare instances.

"To-day my standpoint is practically reversed, and I do not use it any more as a diagnostic agent, but I employ it in all suitable cases for immunizing purposes, and I believe with very encouraging results. The only danger I can see that it might have in the hands of the average practitioner, is in giving too large doses. When we once can get in the market dilutions of various strengths so that the preparation can be directly injected without further dilutions, then there ought not to be any difficulty in its more general employment. At present the making of dilutions for hypodermic application requires an amount of care for which the average physician who treats only isolated cases has hardly the time or inclination. I believe we will also come to the rectal and stomachal application of tuberculin, the good results obtained by this method with my father's tuberculin derivative, tuberculocidine, seem to speak for it.

"As to the choice of tuberculin, I believe that it does not matter much which preparation is used, provided it is prepared from the tubercle culture. (I may have to modify this belief soon.) All the Koch's preparations, the tuberculocidine, Denys' B. F., Beraneck's tuberculin can be used with equal success, provided one begins with a sufficiently small dose and gradually increases it (injecting twice a week), always carefully avoiding reactions. By the latter I do not understand only increase of temperature, but also subjective disturbances as increased cough, malaise, sleeplessness, etc. In most instances the treatment has to be prolonged for many months, but it is very simple, and without inconvenience to the patient, with perfect technique.

"From what I have seen of the results obtained I believe that tuberculin therapy is the treatment par excellence of tuberculosis, although it is yet in its infancy, and never will do away with hygienic and dietetic methods, which in every case must be employed."

Considering the unpleasant results that may follow the injection of tuberculin as a diagnostic measure and the element of error involved, its use does not seem justifiable.

Treatment.—As the successful treatment of pulmonary tuberculosis depends upon the observance of certain rules of living that are apt to be in such marked variance with the daily habits of most of the patients, the difficulty of effecting a cure is apparent.

The progress of the disease being slow and the disability in even rather well advanced cases not being pronounced, the patients are unable to appreciate the necessity of instituting prompt and effective measures for their relief.

The frequent relapses, the months and sometimes years of patient effort required to establish freedom from objective and subjective symptoms, are discouraging to both patient and physician. All patients suffering from pulmonary tuberculosis should begin treatment by rest in bed, for at least six weeks. This initial rest should be taken under conditions that are as near an approach to out-of-doors as it is possible to obtain.

The family as well as the patient should understand that the six weeks' rest will not cure the disease; that its object is to check its progress and give the patient an impetus towards recovery.

It should be made clear that the road to recovery is not likely to be an uninterrupted one, but that occasional periods of one or two weeks in bed are to be expected. If constipation exists it should be relieved at once. Magnesium sulphate in daily teaspoonful doses acts very nicely, and may be continued for two or three weeks. If the patient suffers from nausea or vomiting, relief is most quickly obtained by administering a high enema, consisting of glycerin, half an ounce, magnesium sulphate, half to one ounce, water one quart.

It is surprising to see how promptly nausea, vomiting, and gastric pains disappear under a liberal diet, when the patient is put to bed, and free movement of the bowels is established. For continuous use, when a laxative is needed, fluid extract of cascara sagrada, in five to ten minim doses three times a day, is one of the best and most satisfactory drugs.

For the associated bronchitis, guaiacol carbonate, in five grain doses four times a day, is of value. I have seen some patients improve nicely, who received ichthyol in thirty grain doses three times a day, while in other cases it has seemed to have no effect

The two drugs that have given me the best results in all cases are arsenic and tincture of nux vomica. They may be given singly or combined; arsenic in the form of Fowler's solution in three-drop doses, and tincture of nux vomica in five-drop doses at meal time.

While I believe that serum therapy, combined with better hygienic conditions, will in the future be to tuberculosis what vaccination is to smallpox, I feel that with the present knowledge of tuberculin, it would be better to confine its use to sanatoriums, where the risk of its administration can be reduced to a minimum, and the reaction carefully observed.

However, as many competent men are using it in general practice and believe in its value, I do not think its use should be entirely condemned or thought unsafe in the hands of the general practitioner. In the matter of feeding it should be kept prominently in mind that, with the patient in bed, the stomach will care for an amount of food which,

if taken with the patient going about, would prove disastrous. The diet should consist of three liberal, properly prepared meals a day. In addition the patient should drink one to two quarts of mixed milk and cream, and take from three to a dozen raw eggs during the twenty-four hours. The patient should be instructed to drink the milk slowly. Three or four drams of lime water may be added to the daily supply.

Sleep can often be obtained for those patients who suffer from insomnia by having them take an egg or two and a glass of milk at midnight, or later, if awake. The egg should be broken into a cup, sprinkled with salt, and swallowed. Patients should not be permitted to render the eggs more palatable by the addition of nutmeg, sugar, vinegar, wine, or whiskey, as such measures are almost certain to create a disgust for the eggs, while if prepared as above indicated, the most sensitive patients take them willingly.

In cases that are not past the curative stage, cough subsides under the influence of rest and care, without resort to sedatives. Mixtures that increase bronchial secretions are pernicious.

When profuse hemorrhage occurs, morphine should be administered hypodermically. I do not believe that any other drug has any influence in preventing pulmonary hemorrhage. Among the poor the trained workers of the Visiting Nurses' Association render valuable service to the patient and accomplish a great deal by keeping the other members of the family persevering in their efforts to prevent spread of the infection.

When the patients are out of bed they should be taught to eat slowly and practise deliberation in all physical movements, as such deliberateness tends to conserve nervous energy and favor the accumulation of fat. Success in the treatment of pulmonary tuberculosis depends upon the enthusiasm of the physician and his ability to prevent his patients from becoming lax in their efforts to maintain their physical condition at its highest possible standard.

34 Washington Street.

STUDIES OF JUVENILE CRIMINALS.

By ARTHUR MacDONALD,

WASHINGTON, D. C.

AUTHOR OF "MAN AND ABNORMAL MAN," AND HONORARY PRESIDENT OF THE THIRD INTERNATIONAL CONGRESS OF CRIMINAL ANTHROPOLOGY, OF EUROPE.

The scientific study of crime is in its beginning, but the investigation of criminal youth is still more exceptional. It may therefore be of interest and value to give the results of three studies in juvenile crime. One consists mainly in observations of the physical defects of sixty-five young persons. Another is a more general study of 200 children from six to twelve years of age in a reformatory. The third is a special investigation of a "criminal-born child." While these results are quite incomplete, yet it is hoped that they may serve as a suggestion for further inquiry along these lines.

Some Physical Defects of Sixty-five Young Criminals.—Table No. 1 gives the percentage in order of frequency of some prominent physical defects of sixty-five young criminals.[2]

Some of these defects are normal in lower races and in animals, and favor the theory that the criminal is a reversion to a lower type. While it is doubtless true that these criminals have more physical defects than people in general, yet it is impossible to say just how many more, since a sufficient number of people in general have not as yet been studied with thoroughness adequate to warrant trustworthy comparison. Notwithstanding the advancement of this age, the serious study of normal living man has hardly commenced.[3]

TABLE 1.

Per Cent.	Defects	Per Cent	Defects
75	Arm-reach greater than height.	37	Antitragus of ear large
68	Projection of lower jaw.	37	Helix of ear rudimentary or absent.
68	Defective palate.	35	Thick lips.
65	Ears standing out.	34	Face not symmetrical
65	Ears adherent.	34	Length of fingers greater than that of palm.
56	Head defective in shape	32	Mouth kept open
53	Bumps on forehead prominent.	28	Skin dark.
52	Prominent cheek bones.	25	Nose crooked.
51	Teeth defective.	21	Hairy skin.
37	Occipital protuberance large.		

Antecedents.—Of the sixty-five criminals studied it was possible to obtain data in only forty-five cases. The number of defects is doubtless much below the reality, as there are so many temptations to conceal them. The most frequent hereditary taints are: (1) Nervous diseases, 95 per cent.; (2) lung diseases, 64 per cent.; (3) alcoholism, 62 per cent.; (4) insanity, 47 per cent.; (5) epilepsy, 32 per cent.; (6) mental backwardness, 20 per cent.

TABLE 2.

Antecedents of 45 young criminals	No	Per Cent.
Insanity—		
Father	0	0.0
Mother	4	8.88
Paternal and maternal relatives	17	37.77
In all	21	46.66
Mental backwardness	9	20.00
Epilepsy or convulsions	16	32.00
Hysteria	12	26.66
Nervous character—		
Father	17	37.77
Mother	23	51.51
Other relatives	35	77.77
Nervous diseases—		
Father	3	6.66
Mother	9	13.33
Other relatives	43	95.55
Alcoholism—		
Father	22	43.88
Mother	3	6.55
Other relatives	28	62.22
Excess of coffee drinking—		
Father	0	20.00
Mother	0	13.33
Other relatives	0	20.00
Lung diseases—		
Father	8	17.77
Mother	2	4.44
Other relatives	29	64.44

The prominence of nervous diseases suggests the results of extreme pressure due to the abnormal conditions of modern life. The author has indicated this in detail in Senate Document, No. 12, 58th Congress, 3d Session, entitled, "Statistics of Crime, Suicides, and Insanity."

A Study of 200 Children from 6 to 12 Years of Age in a Reformatory.—Of these children 134 were abandoned children, 13 had been in the poorhouse, and the majority of these had committed crime before, 44 had been vagabonds, and 19 beggars, 146 thieves, and 33 embezzlers. The social surroundings of those children were substantially the same, coming from the lower classes and being in the same institution, having the same school advantages, and being born in the same city.

In 10 cases the father was insane, in 14 the mother; epilepsy was found in the father in 11 instances, in the mother 15 times, and in sisters and brothers 7 times. Other nervous diseases were found in the father in 2 cases, and in the mother in 24 cases. In 78 cases the father was an alcoholic, in 5 the mother, and in 2 both parents; 22½ per cent. (45) were illegitimate, about 10 per cent. more than the general average for the city.

In 47 cases the father was dead, in 29 the mother, and in 13 both parents; in 15 cases the father and mother lived apart, and in 4 cases they lived in concubinage. There now remain 80 cases in which the children might have normal home training, but unfortunately in 48 of these the father, in 24 the mother, and in 15 both parents, left home in the daytime to go out to work. In 6 cases extreme poverty and in 15 sickness of parents prevented the children from having any education and training.

It is noteworthy that so few of the parents were criminals; in 8 cases the father and in 7 the mother had been convicted of crime.

In 24 children rickets was present, in 9 hereditary syphilis, in 12 scrofula, in 4 hydrocephalus, in 49 there were found injuries or wounds on the head, 15 of which must have affected the mental condition. In 25 cases there were chronic diseases.

In at least 68 children there was mental weakness, of these 35 were morally deficient, 7 were hysterical, 5 had paronoia.

In 52 cases the anterior circumference of the heart was greater than the posterior, and in 122 instances the reverse was true; in 26 cases the two circumferences were equal, 128 were brachycephalic, 58 mesocephalic, and 14 dolechocephalic.

There were 4 cases of microcephaly, 9 of trochocephaly, 36 showed a degree of asymmetry, 49 limbose coronal suture, 32 bulging out of the parietal eminence, 14 a depression in the parietal occipital region, 21 with retreating forehead, 11 with large superciliary ridges, 12 with temporal muscle, 19 with irregular limits to where the hair begins, 30 with wrinkles in the forehead, 12 with asymmetrical spots in the iris, 30 with adherent ear lobes, 17 with ears unsymmetrical as to size and insertion, 31 with Darwinian nodules, 20 with Wildermuth ear, 14 with decayed teeth, 21 with gap in row of teeth, 39 with irregularly inserted teeth, 43 with high standing gums, 41 with torsus palatinus, 26 with birthmarks. Other stigmata were found in 134 cases. Of the 83 normal children there were only 5 with no stigmata.

There was no unusual number with abnormal sensibilities. There was no conspicuous obtuseness to pain. The general physical development of the children was good, corresponding to the favorable hygienic conditions in which they lived. A striking physical development was noted in 17 cases, and a very defective one in 7 cases; 4 were left-handed and one ambidextrous.

Nervous abnormalities were not specially frequent; 10 had strabismus, 17 difference of pupils, 23 facial irregularities, 16 with no abdominal reflex, 6 had convulsive tics and 8 stuttered, 17 others had various nervous abnormalities.

Out of the 200, 83 were tatooed, a relatively large number. The tatooing consisted in the simplest forms, as heart, arrow, crown, coat of arms, initials, banner, cross, anvil, anchor, ship, sailor, dolphin, snake, women bracelet, ring, head, athlete, dumbbell, indian, tomahawk, horse's head, clown, half-moon. The location of the tatooing was on the arm, except in three cases in which it was on the breast. Of the 83 normal children 32 were tatooed; of the 68 mentally defective 21 were tatooed. The cause of the tatooing was due mostly to imitation, it being a common practice in the institution.

We will add here a few tables giving the results of some minor studies. Table 3 gives the results of study of the ears in different classes of people by Gradenigo.

TABLE 3

Ear	Criminal, Per Cent.	Normal Per Cent.		Insane, Per Cent.
		Men	Women	
Pavillion regular	20.2	50.55	62.	46.
Lobe adherent	25.	20.	13.	30.
Outjutting	24.	12.5	3.2	4.2
Of Wildermuth	18.	0.2	0.12	6.26
Antihelix prominent	14.2	.....	11.5	26.

Table 4 gives the results of the investigations of Ottolenghi and Maupaté as regards the nose in thieves.

TABLE 4

Nose in Thieves	Ottolenghi, Per Cent.	Maupaté, Per Cent.
Rectilinear	40.	50.
Concave	23.	37.5
Base elevated	32.13	31.25
Short	30.92	.....
Large	53.28	18.75
Flat	31.33	.....
Crooked	37.5	37.5

It has been said that thieves have large noses and swindlers pointed noses. But the number investigated is so small as to make such a conclusion merely tentative.

Marro gives in Table 5 the antecedents of criminals indicating the possible influence of hereditary conditions. Alcoholism, cerebrospinal diseases, and immorality in character play the most prominent part.

TABLE 5

Antecedents	Father, Per Cent.	Mother, Per Cent.	Ancestors, Paternal Per Cent.	Ancestors, Maternal Per Cent.
Alcoholism	41.	5.1	.....	.....
Old age	32.	17.	.....	.....
Insanity	9.2	3.3	2.7	4.1
Cerebrospinal diseases	21.1	18.	.....	.....
Epilepsy	1.7	.9	0.1	0.1
Immorality or violent temper	22.6	11.3	.....	.....
Consumption	5.1	10.1	.....	.....
Criminality	3.3	0.3	.....	.....

According to Lombroso and Blomberg those addicted to the use of alcoholic liquors are frequent among the antecedents of thieves, as indicated in Table 6.

TABLE 6

Epilepsy in Parents of	Lombroso, Per Cent.	Marro, Per Cent.
Thieves	2.1	3.3
Violators	1.2	.....
Suicide of Parents:		
Thieves	5.	5.1
Violators	3.9	.....
Insanity in Parents:		
Thieves	0.4	14.5
Parents Addicted to Drink:		
Thieves	14.3	46.

The Criminal-born Child.—In accordance with the belief of Dietrich,[4] the child to be described illustrates the criminal type.

Carlo was ten years old, 110 cm. in height, weight 18 kilograms, length of head 170 mm., width of head 140 mm., circumference of head 505 mm. The child was very short for its age, its head was very large (macrocephaly), its eyes large, glistening and projecting prominently from the orbits. A little down covered the forehead. The child had a snub nose, the sutures of the head were prominent and easy to feel, the teeth were very small and irregularly arranged, the zygoma were prominent. The visual field was abnormal, showing peripheral scotoma. The esthesiometer gave 2.2 on right wrist, 2 on left wrist, and 2 on the tongue. Electrical sen-

sibility on right 40.0, on left 15.0; sensibility to pain on right 15.0, on left 25.0. The father died of pneumonia, at 41; he was a strong drinker; the mother died at 31 of uterine trouble, was always sickly; had seven children, of whom three are living.

Right after its birth the child was difficult to treat and caused the nurse much trouble; at eighteen months of age the child began secret habits, and no way could be found to prevent it. When larger he would bite and scratch other children. He began to drink wine. He was a liar. He began to steal when two years of age. The child since his birth had been subject to starting up in its sleep and to spells of vertigo. He was very uncleanly. At school his desire to steal increased continually; he would steal from his schoolmates; he would put his hand into the pocket of his sister, stealing her money to buy candy. He read bad books. He was very fond of his aunt, and was sent to her after the death of his mother. He had an intense hatred for anyone who did him the least wrong, and sought opportunity for revenge.

According to Dietrich the following are some of the principal stigmata of the criminal type: Plagiocephaly, megalocephaly, microcephaly, prognathism, irregularity of teeth, ears outstanding, hypertrophy of genital organs, asymmetry of face, inequality of body, especially the eyes, ears, hands, and feet. In many cases bad secret habits are practised from the earliest periods. It should be noted that no individual would have all those stigmata, yet would have some of them in a striking way.

TREATMENT OF MALARIA IN THE VICINITY OF NEW YORK CITY.

By WILLIAM STUMP, A.M., M.D.,

LARCHMONT, N. Y.

Of all human diseases, tertian malaria is one of the most amenable to treatment. That the ordinary treatment by quinine in divided doses is finally effectual, is undeniable, but that such administration is the best, is debatable. I believe in the light of the actual pathology of the condition, and from my own experience, that the usual treatment is susceptible of radical improvement.

We know that the cause of the disease is the plasmodium, a single cell protozoön, and that it is introduced into the system by the bite of one genus of mosquito, the Anopheles. When the organism is transferred to the human body from the salivary glands of the Anopheles it enters the red corpuscles, and while in the red corpuscles grows, so that at the end of forty-eight hours it has attained its full size, when it reproduces itself by splitting up into 15 or 20 new organisms which, breaking forth from the enveloping red corpuscle, escape into the serum. At the same time a toxin is liberated, causing the paroxysm which we commonly call the "chill." At this time each of the newborn organisms seeks out a future home, enters a red corpuscle, grows, and at the end of another 48 hours finishes its cycle and has reproduced. Thus we have our paroxysm recurring every other day at the same hour.

Knowing the life history of the plasmodium within the human body and knowing that it is enveloped in a protective sac as it were, and is only free in the serum at the time of segmentation, does it not seem logical to administer the remedy at the time when it will kill the organism? In the ordinary manner of treatment it has been the custom to give quinine in divided doses at intervals of three or four hours, thus maintaining a constant but low quinine percentage in the blood plasma. The result is that a certain number of the organisms are retarded in their development or killed, yet many spores find refuge in red cells and the disease is uncured.

Now were the quinine so administered as to have the maximum saturation at the time when the organisms were young and tender, were extracellular, and particularly vulnerable to the toxic effect of the quinine, the disease would be much shorter and more effectually eradicated.

My method of administering quinine in these cases is to give it in solution one hour before the expected paroxysm, to give it in sufficiently large dose to kill the maximum number of the organisms, and to follow up with the same amount at the same time for those three or four successive days on which the paroxysm would have occurred. I then give the same amount two weeks later for two more successive days on which the chill would have occurred. I have found that the ordinary tertian malaria, such as we meet with in the vicinity of New York, always responds to treatment in one dose, and there will be no relapse, provided the directions are carefully followed by the patient. I usually give five grains for each fifty pounds of body weight; thus the average patient will receive fifteen grains. After having examined the blood, which I always do, I write out a schedule to be followed minutely.

We will assume that the paroxysm was at 10 o'clock on Monday, May 27, and that the patient has taken quinine in 5-grain doses every three or four hours. We know that on Wednesday, May 29, he will probably have another chill at 10 o'clock. He is given at once calomel to be followed by a saline. I write the following:

℞ Quininæ Sulph., ...5iss
Acid Sulph. dilut. to dissolve
Aquæ 5ij
M. Sig. One tablespoonful as directed.

I then hand the following schedule to the patient, warning him to follow it carefully: Take one tablespoonful at 9 o'clock on Wednesday, May 29; Friday, May 31; Sunday, June 2; Tuesday, June 4; Thursday, June 20; Saturday, June 22.

The reason for the second course of quinine at an interval of two weeks is that any stray or latent organism not destroyed by the first course may be eradicated. During the two weeks' interval should a fresh paroxysm occur it is usually found by consulting the calendar that such paroxysm belongs to the cycle of an entirely distinct infection from the one originally treated.

The method outlined has the advantages of curing in the shortest possible time, with the least risk of subsequent relapse, and with the minimum drugging of the patient.

Résumé.—Examine the blood in every case.

Flush the alimentary tract.

Give quinine in solution, 5 grains for each 50 pounds of body weight, one hour before the expected chill, and follow with the same dose in chronological sequence.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., 51 FIFTH AVENUE

New York, July 20, 1907.

THE SIGNIFICANCE OF MONGOLIAN PIGMENT SPOTS.

For centuries Japanese writers have discussed the nearly constant presence in the sacral region of irregular areas of bluish pigmentation in recently born children of their race. The occurrence of this phenomenon is but little known among our medical men, and still less is known of its meaning and distribution. The spots vary in size from a small coin to that of an expanded hand, and while usually found over the sacrum, isolated ones may occasionally be found in other parts of the body. They are not raised above the surrounding skin nor are they influenced by pressure. In nearly all cases this pigmentation is present at birth, though it may not appear until a few weeks after birth; it then gradually fades, leaving no trace after a few years. Similar areas are found in ninety-seven per cent. of pure Chinese and in other Mongolian peoples. Microscopical examinations of these spots in the Japanese and Chinese have revealed large spindle and stellate-shaped pigment cells deep in the corium.

In 1903 Adachi instituted a search for these cells in the skin of white children. He found deep corium cells (similar to those found in Japanese and Chinese with blue spots), only in limited areas, usually in the sacral region, in ten out of twenty-four white children up to two and a quarter years of age, though blue spots could not be seen in any of them. Other observers, however, have reported well-authenticated cases of blue spots in pure white children. Definite reports of similar spots have also been obtained from various other races and peoples (Malayans, Hawaiians, etc). J. Brennemann, writing in the *Archives of Pediatrics* for June, 1907, says he has recently examined forty American negro children under one year of age. Thirty-six showed well-marked areas of pigmentation, the area varying in size from that of a dime to that of a dollar, and being usually found in the sacral region; the color varied from a bluish gray to a deep violet color. It was impossible to establish any definite relationship between the intensity of these spots and the amount of white blood in any given case, because of the uncertainty concerning ancestors more than one or two generations removed. He examined skin from over the sacrum and from the ventral surface of the chest in a still-born negro child, in which no blue spots were seen. In the piece from the chest no pigment could be found in the corium, while in that from the sacrum the deep layers of the corium were thickly strewn with large pigment cells closely resembling those described in Japanese, Chinese, and Caucasian children. It seems certain, therefore, that these spots, which were formerly considered a distinct Mongolian racial characteristic, are a human characteristic found in different degrees in all races. The view held by Adachi that we have here to deal with a rudimentary formation can alone explain them satisfactorily.

In the white man these deeper lying pigment cells of the corium exist as a localized transitory condition. In darker races, where there is more pigment in general, the cells are often present in sufficient number or degree of concentration to show through the overlying layers, and thus appear to the eye as blue pigment spots; in the race of least pigment, the Caucasian, the same pigment cells are present, but only exceptionally occur in sufficient numbers to be visible as the blue spot. They must not, therefore, be considered as an exclusive race characteristic, but are to be accorded the same value as other racial traits—color, hair, etc. Their presence or absence in given cases leads to highly probable, but not positive determination as to race or to degree of admixture.

THE RELATION OF TRANSIENT GLYCOSURIA TO DIABETES.

Von Noorden has recently expressed the opinion that transient glycosuria, the reason for which does not obviously lie in a diet excessively rich in sugar, has a tendency to be followed by diabetes. As this undoubtedly occurs in a number of cases it is important to know which ones are followed by diabetes, so that by proper treatment the latter may possibly be prevented. In the June number of the *American Journal of the Medical Sciences*, T. B. Barringer and J. C. Roper endeavor to show how many and which cases of spontaneous transient glycosuria develop later into diabetes. They selected from the records of a life insurance company all cases showing a glycosuria of one per cent. or less during the years 1900 and 1901; twenty of these could be followed up closely. In 1906 all but two patients were in apparent health, the one having a chronic nephritis and the other tabes. Of five patients who showed sugar in the urine previous to 1900, two had developed a constant slight glycosuria and could be called diabetic, although the glycosuria was the only symptom present. Of the fifteen in whom sugar was first found in 1900 and 1901, two had developed a constant slight glycosuria, but showed no other diabetic symptoms. Thus four developed mild diabetes in from five to eight years.

Barringer and Roper showed furthermore that there exists a relation between spontaneous transient glycosuria and glycosuria e saccharo. When one hundred grams of glycose or cane sugar was given to a healthy individual, usually no glucose was found in the urine, and it ordinarily required 150 to 200 grams of either substance to produce glycosuria in a normal individual. Hence the production of glycosuria by the ingestion of one hundred grams would prove conclusively that the assimilation limit for glucose was lowered. Eighteen of the twenty patients received one hundred grams of glucose three hours after breakfast, and their urine was examined two or three hours later, no food being taken in the interval. The four diabetics showed an alimentary

glycosuria of from one to three per cent., an additional evidence of the correctness of the diagnosis. Five others showed from one to four-tenths per cent. glucose, while two showed traces, but not enough for quantitative analysis; in seven patients the urine examinations were negative. Thus fifty per cent. showed a disturbed sugar metabolism five years after the first discovery of sugar; four were surely diabetics, five were probable diabetics, and nine were surely nondiabetics. Eighteen of the twenty were examined again after sugar had been first found, and eleven showed a glycosuria on this second examination. These eleven included the four diabetics and four of the five probable diabetics, which exemplifies the prognostic value of a repeated detection of traces of sugar. All but one of the nine cases which showed alimentary glycosuria also showed sugar on repeated examination. It is thus seen that alimentary glycosuria arising from glucose or cane sugar, provided the test is properly conducted and repeated at intervals, affords an indication as to whether the spontaneous transient glycosuria will develop into diabetes. Those patients in whom the glucose reaction is repeatedly positive should be put on a restricted diet, even though the spontaneous glycosuria has not recurred; the others in whom the reaction is negative require no treatment.

As regards the occurrence of non-diabetic glycosuria, however, A. L. Benedict (*American Medicine*, May, 1907) thinks it has been overestimated. In 3,500 urine examinations he did not find a non-diabetic glycosuria once, except such as might be explained by excessive ingestion of sugar, three cases of Addison's disease, ten of Graves' disease, and several pregnant and nursing women being included. He feels certain that the idea that such cases are at all common rests on errors of technique, and believes that any suggestion of sugar should be checked by the picronitric acid and fermentation tests.

THE PRODUCTION OF SEX.

An explanation of the causes which govern the production of sex has been sought for from earliest times. The ancient belief, which still holds among some of the laity, that the right ovary gives rise to male and the left to female children, was effectually denied over a century ago and has more recently been proved to be false by the fact that after a unilateral oophorectomy, a woman could bear children of either sex. Statistics have shown that the male sex of the human species exceeds the female by a fairly constant proportion, from fifty to sixty per thousand births, and this is another fact which has not been accounted for satisfactorily. The period of time at which the sex of the offspring is determined has also been the subject of much attention, and a number of hypotheses have been advanced to provide a solution of this problem. Whether sex is determined in the ovum before conception takes place or at the moment of its occurrence, or finally at some later period of development, is still unknown. The idea that it might be dependent upon external circumstances during the period of development has served as a basis for a number of investigators to formulate a theory which shall have a practical value, but none of these theories, not even the much heralded one of Schenk, has been satisfactorily substantiated. The latter's experiments have stimulated further experimental research, however, among which considerable interest attaches to the recent observations of Peham (*Monatsschrift für Geburtshülfe und Gynäkologie*, April, 1907) on the influence of ovarian substance on the sexual functions of animals.

Peham's experiments consisted in feeding ovarian extract to rabbits during a number of generations, his observations extending over a period of three years. Successive broods of females were fed with this substance, but in every instance the results were negative as regards the production of either sex in greater proportion. It does not seem possible therefore that by feeding with ovarian substance the germ cells in the ovary can be stimulated to form one kind of ovum in preference to another, and the laws of nature which govern the production of the sexes remains unsolved at the present. It is perhaps just as well that we cannot interfere in a process which, if it could be controlled, might result in more harm than good.

THE SURGICAL TREATMENT OF GASTRIC ULCER.

In regard to the treatment of gastric ulcer both surgeons and internists seem to agree that surgical measures should be resorted to when persistent and thorough internal treatment has brought about but little or only temporary improvement and the patient's life has been rendered burdensome through pain, vomiting, dyspepsia, etc. While this view is now pretty universally accepted, there is still difference of opinion in regard to the precise means that shall be resorted to by the surgeon to whose care an operative case of the disease has been referred. Some surgeons, such as Rydygier, still regard resection of the separate ulcers as the most widely applicable procedure, but there are many objections to this view, and at present the majority of operators undoubtedly prefer gastroenterostomy as the routine measure. The manner in which this operation exerts its curative influence is not altogether clear, however. It was formerly supposed that as a result of the anastomosis the stomach was subjected to a species of drainage which insured the rapid passage of the food magma into the intestine, but Hildebrandt (*Berliner klinische Wochenschrift*, June 24, 1907) accepts the theory of Katzenstein, who believes that this element is operative but little, or not at all. He states that if the stomach is inflated after a gastroenterostomy it is found that there is an air-tight closure of the fistulous opening, and Katzenstein has also shown that the ingesta remain in the stomach just as long after a gastroenterostomy has been done as under normal conditions. The chemical aspects of digestion undergo modification, however, as the hyperacidity is reduced or entirely relieved through the fact that the alkaline intestinal juice periodically flows back into the stomach and reduces the amount of free hydrochloric acid in that viscus. According to this view, the operation of gastroenterostomy is to be regarded not simply as a palliative measure, but as one which is directly curative, since it tends to remove one of the underlying etiological factors or concomitants of the lesion.

Obstetrical Operations on Animals.

The value of the practice in surgical technique to be obtained by performing operations on animals is self-evident, and the addition of courses in operative surgery of this sort is a noteworthy improvement in the surgical instruction given in many of our medical schools. It has been suggested that equally desirable training in obstetrics may be derived from the performance of the usual and unusual manipulations and operative procedures on the larger domestic animals, such as the sheep and cow. Sellheim has recently (*Deutsche medizinische Wochenschrift*, May 30, 1907) described a method for practising the operation of pubiotomy on the sheep, and in a subsequent publication in the *Münchener medizinische Wochenschrift*, June 18, 1907, he urges young medical practitioners to familiarize themselves with the management of certain obstetrical emergencies by rendering active assistance during parturition in the cow. The manual removal of the retained placenta is one of the most serious of the more ordinary obstetrical operations, and is likely to tax severely the skill and judgment of the operator the first time he is called upon to perform it. Valuable practice in intrauterine manipulations of this sort may be had by removing the placenta and membranes of the cow. In this animal the placenta is multiple, often being made up of sixty or one hundred separate portions, and in the process of removing this mass of material the opportunities for appreciating the difficulties of the corresponding procedure in the human female are manifold.

The Eyesight of Chauffeurs.

The announcement that a regulation is about to be enacted in Germany requiring chauffeurs to exhibit evidence of having successfully passed an examination of their eyesight before licenses to drive motor cars will be granted or renewed, involves a suggestion that appeals to common sense and a regard for public safety. The desirability of normal visual acuity in chauffeurs is self-evident, and restrictions in their regard similar to those applying to railway employees would seem to be a not unreasonable requirement. Feilchenfeld, in discussing the subject in the *Deutsche medizinische Wochenschrift*, June 20, 1907, calls attention to another feature of the question which is not without importance. Owing, he says, to the short period of apprenticeship required and the comparatively high rate of remuneration, crowds of individuals who have been unsuccessful in other occupations are taking up that of driving motor vehicles. Among these are many who are physically deficient, notably in the matter of eyesight, and legal regulation of those eligible for work of this sort is not only desirable but extremely necessary. The very great frequency of automobile accidents, often under what seem to be rather mysterious circumstances, appears to indicate that the physical incapacities of those driving the machines may contribute in no small degree to the dangers inherent to the abuse of this means of locomotion.

A Medicolegal Mayor of San Francisco.—Dr. Edward R. Taylor, physician and lawyer, Dean of the Hastings Law College and of the University of California, was elected Mayor of San Francisco by the Board of Supervisors on July 16. One of the arbitrary acts of former Mayor Eugene Schmitz, now in jail, was the turning out of the health board of the city because it dared to do its duty, in opposition to his commands, in acknowledging the presence of plague in the city and taking measures to prevent its spread.

News of the Week.

A School for the Deaf.—The Board of Education has authorized the establishment of a school for the deaf, which is to be located in the building at 225 East Twenty-third street, now occupied by the Stuyvesant High School. This school will move into a new building in the fall, and it is expected that by September accommodations will be provided for 175 deaf pupils. It is intended to teach lip reading and oral speech exclusively, and to make manual training and industrial work a prominent feature in the courses of instruction. When necessary, provision is to be made for the payment of carfares of children coming from a distance.

Food Preservatives and Coloring Matters.—The Department of Agriculture on July 12 published a decision in regard to the use of chemicals in food products. Common salt, sugar, wood smoke, potable distilled liquors, vinegar, and condiments may be used as food preservatives, and pending further investigation the use of saltpetre will be allowed. Pending further study of the use of sulphur dioxide the presence of small amounts of this preservative will not be regarded as cause for prosecution. The use of sodium benzoate will be permitted for the present, but its presence must be stated on the label. Certain coal tar dyes are specified as permissible for coloring purposes, and the use of small amounts of copper salts for greening canned vegetables is permitted providing the label bears the statement that these salts are present.

Bequests to Cincinnati Institutions.—The will of Francis T. White, formerly of Cincinnati, Ohio, filed in the Surrogate's office of this city, gives $2,500 to the Cincinnati Orphan Asylum and like sums to the Cincinnati Union Bethel, the Children's Home, the Widows' Home, and the Home for Aged Men, also of Cincinnati. The Children's Aid Society of New York is to receive $2,500.

Chicago College Buys Central Site.—The Chicago Eye, Ear, Nose, and Throat College has completed the purchase of a site, and within a year will begin the construction of an eight-story building, fitted for its uses, to cost from $125,000 to $150,000. The college owns the property at the southeast corner of Washington and Franklin streets, which adjoins the site just bought, so that it has a frontage on Washington street of 40½ feet and 80½ feet on Franklin.

The Fourth of July in Chicago.—The elaborate preparations for the Fourth of July by the Chief of Hospitals and Ambulance Service—which included a volunteer corps of twenty-six senior students from the College of Physicians and Surgeons and the Rush Medical College, happily proved largely unnecessary. Thanks chiefly to the agitation by the public press, the repeated warnings as to the danger of explosives, advice as to the handling of fireworks and the importance of prompt treatment of wounds, the Fourth of July casualties were fewer in number than for many years.

State Hospital Reports.—Governor Hughes has approved the Armstrong bill providing that the proceeds of the sales of the manufactures and products of the State Hospitals shall be reported monthly to the State Treasurer by the State Lunacy Commission.

Bellevue Hospital Decision.—The State Board of Charities has adopted a resolution requesting the Attorney-General to take an appeal from the decision of Supreme Court Justice Pitts in the case

against the Bellevue and allied hospitals of New York City. The Board sought to compel these hospitals to submit their plans for building improvements for its approval, but Justice Pitts decided that they need not do so.

Plague in India.—According to the London correspondent of the *New York Times,* the deaths from plague in India have been greater during the first six months of 1907 than in any previous entire year since 1896, not even excepting 1904, when there were 1,022,299 deaths. From January 1 to June 30, 1907, there were 1,060,067 deaths. The mortality from plague last year was 332,181, and the total mortality since 1896 to June 30, 1907, was 5,471,309.

Tuberculosis Sanatoria in Germany.—The recent report of the German committee for the restriction of tuberculosis shows that great progress has been made during the past year in providing accommodations for the tuberculous poor. There are now in Germany 87 public sanatoria with 4,822 beds, and 35 private sanatoria with 2,118 beds, numbers which are said to exceed the total of all the other public sanatoria of Europe combined. Eleven other public sanatoria with 800 beds are in the course of construction. There are also 17 institutions with 650 beds for children with advanced tuberculosis, and 67 institutions with 6,092 beds for less advanced cases of general tuberculosis in children.

Rubber Stoppers in Germany.—Owing to the fact that it is now considered that rubber containing antimony is not dangerous to health, the German government has rescinded a former measure making it unlawful to use rubber of this sort in connection with containers of food stuffs.

British Medical Association.—The seventy-fifth annual meeting of this Association will be held at Exeter, July 27 to August 2, 1907, under the presidency of Dr. Richard Andrews Reeve, Dean of the Faculty of Medicine, University of Toronto. The President-elect is Dr. Henry Davy, Physician, Royal Devon and Exeter Hospital. The address in medicine will be delivered by William Hale White, M.D., F.R.C.P., Lond.; the address in surgery by Mr. Henry Trentham Butlin, D.C.L., F.R.C.S., Eng., and the popular lecture will be delivered by Sir John William Moore, M.D., D.Sc., F.R.C.P., Irel.

Second International Congress on School Hygiene.—This will be held in London on August 5 to 10, 1907, under the patronage of the King and many other eminent personages. The preliminary program provides for sessions in ten different sections devoted to various aspects of school hygiene, and exhibits of interest in this connection have been arranged for. The general secretaries are Dr. James Kerr and Mr. E. White Wallis, Royal Sanitary Institute, Margaret street, London, W. The president of the committee for the United States is Dr. Henry P. Walcott of Boston, and the secretary is Dr. Thomas A. Storey of Boston.

The Medical Society of the County of Dutchess held its quarterly meeting on July 10, 1907, at the Hudson River State Hospital, Poughkeepsie, under the presidency of Dr. D. H. Mackenzie of Millbrook, N. Y. Dr. Charles E. Nammack of New York City, president of the First District Branch of the State Medical Society, addressed the members and guests on the subject of the legal, professional, and social advantages of the present plan of county, State, and national organization. The scientific portion of the program consisted of papers on the following subjects: "Commitment of the Insane," by Dr. Charles W. Pilgrim; "Anxiety Depressions," by Dr. Frederick W. Parsons; "Improper Commitments of Alcoholics," by Dr. Clinton J. Hyde; "Training Schools in State Hospitals," by Dr. Isham G. Harris. The papers were discussed by Drs. Borst, Cotter, Frederick J. Mann, Kruse, and Nammack. Over seventy members and guests were in attendance.

Rutland County (Vt.) Medical Society.—At the annual meeting of this organization held in Rutland on July 9, officers as follows were elected for the ensuing year: *President,* Dr. A. H. Bellerose of Rutland; *Vice-President,* Dr. J. W. Estabrook of Brandon; *Secretary,* Dr. C. F. Bail of Rutland; *Treasurer,* Dr. H. R. Ryan of Rutland.

Somerset County (Me.) Medical Association.—The forty-third annual meeting of this association was held in Skowhegan on June 27. Officers were elected as follows: *President,* Dr. W. F. Stinchfield of Skowhegan; *Vice-President,* Dr. W. S. Milliken of Madison; *Secretary and Treasurer,* Dr. H. C. Taggart of Skowhegan.

Missouri Valley Medical Society.—The twentieth annual meeting of this society will be held in the city of Council Bluffs, Iowa, on Thursday and Friday, September 5 and 6, 1907. In addition to the regular program, visiting physicians will be guests of the Carnival Association, which will give its annual fair at this time, lasting the entire week. The arrangements are in the hands of a committee of which Dr. Donald Macrae is chairman. The president of the society is Dr. O. Beverley Campbell, and the secretary is Dr. Chas. W. Fassett of St. Joseph, Mo.

Death of Sir William Perkin.—Sir William Henry Perkin, the founder of the chemistry of the aniline dyes died in London on July 14, at the age of sixty-nine years. Last year the jubilee of his discovery of the color mauve in 1856 was celebrated in this country and in England. On the occasion of his visit to this country in October, a Perkin Medal was instituted, to be awarded each year to an American research worker in chemistry; a reference library was founded at the Chemists' Club of this city, and to Sir William himself were presented the first impression of the medal named after him and a silver tea set. The degree of LL.D. was also given to him by Johns Hopkins University.

Death of Sir William Broadbent.—Dr. Sir William Henry Broadbent, physician in ordinary to the King and Prince of Wales and consulting physician to St. Mary's Hospital, Paddington, and other London hospitals, died on July 10 at the age of 72 years. Dr. Broadbent was a prominent London consultant and was well known for his works on diseases of the heart. He was at various times president of the Harveian Society, Medical Society of London, Clinical Society, and Neurological Society. He was a Knight Commander of the Royal Victorian Order and a Commander of the Legion of Honor, and held several honorary university degrees.

Obituary Notes.—Dr. William LeGrange Ralph of Washington died on July 8 at the age of fifty-six years. He was born in this State, and was graduated from the College of Physicians and Surgeons in 1879. He practised for some years in Utica until obliged to give up active work on account of ill health, and then turned his attention to the study of natural history. He made valuable collections of birds' eggs and nests, which he presented to the National Museum in Washington, and since 1897 he had been curator of that section of the Museum.

Dr. Ellie Barnaud of Brockton, Mass., died on July 2, at the age of fifty-seven years. He was born in France, but came to Canada at the age of twenty-one years and received his medical education at Laval University, Montreal. He practised for many years in Spencer, Mass., and then removed to Worcester. Five years ago he became a resident of Brockton.

Dr. Eugene A. Bassett of Chicago died at Barre, Mass., on July 6 of nephritis, at the age of sixty-seven years. He was born in Templeton, but grew up in Barre, and received his medical degree from the Harvard Medical School. He had practised in Chicago for about eighteen years.

Dr. Acland W. H. Oronhyatekha, son of the late Dr. Oronhyatekha, died suddenly on July 8, at the age of thirty-eight years. He was born in Frankford, Ont., and was graduated in medicine from Trinity College, Toronto, fourteen years ago.

Dr. William Miller of Davenport, Ia., died on July 5, at the age of fifty-nine years. He was born in Germany, and in 1869 came to this country. He was a graduate of the Iowa State University.

Dr. W. M. Price of Florence, Ala., died at an advanced age on July 2, as the result of a long illness following a paralytic stroke. Dr. Price had practised for many years in Florence, and had served numerous terms as president of the County Medical Society.

Dr. William Greaves of Northfield, Minn., died on July 2, at the age of sixty years. He was graduated from the medical department of the University of Michigan at Ann Arbor in 1871, and had practised in Northfield for over thirty years.

Dr. Ralph P. Stubbs died at Wilmington, Del., on July 7, at the age of thirty-two years. He was graduated from the medical department of the University of Pennsylvania in the class of 1897.

Dr. George A. Sweeney died at Chester, Pa., on July 8, at the age of thirty-three years. He was graduated from the medical department of the University of Pennsylvania with the class of 1898.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

KING'S BIRTHDAY HONOR LIST—SLEEPING SICKNESS CONFERENCE—CONSERVATIVE SURGERY OF THE ABDOMEN (CAVENDISH LECTURE)—NURSING—ALCOHOL—FOOD REFORM LEAGUE—ST. THOMAS' HOSPITAL PRIZES—OBITUARY, BENNETT OF DUBLIN.

London, June 28, 1907.

A long list of honors conferred by the King in celebration of his official birthday—the day appointed for the purpose, which is not the real birthday—was issued last night. There are four new peerages and as many privy councillorships, eleven baronetcies and thirty-three knighthoods. Among the last you will find Swanzy of Dublin and Alderman Crosby, M.D., of London. In the service honorary are Sir W. MacGregor, M.D., K.C.M.G., promoted to the grand cross of the order; Dr. J. A. Ewing, F.R.S., to be C.B. Surgeon-General Trevor, P.M.D., Western India, to the same distinction. Prof. Ray Lankester receives the K.C.B.

The International Conference on Sleeping Sickness concluded its labors on Monday, having had seven sittings in all. Of these, four were plenary meetings, two of administrative, and one of medical committees. A number of resolutions dealing with proposed preventive measures were agreed to, but with the exception of the British representatives none of the delegates had full powers, so that no formal convention could be entered into. It was proposed that another conference should assemble in the autumn, at which the delegates should be provided with full powers. Perhaps the most far reaching recommendation was the establishment in London of a permanent central bureau to collect material and take the initiative in reference to all international questions in relation to the disease and to fix the dates and places of meeting of future conferences. This central bureau was further to be assisted by a similar national office in each country concerned. Some recommendations of the medical committee as to the prosecution of research were not endorsed by the full conference, in consequence of opposition on the part of the German delegates, though it is hard to imagine why.

Is the vermiform appendix of any use? This question was touched in the Cavendish lecture, which was delivered by Mr. Keetley on the 21st inst. His discourse embraced, indeed, the whole subject of conservative surgery in abdominal operations, and he pointed out that while some surgeons may be ready to remove organs, others may be too anxious to retain them. Having referred to Treves' first paper in 1888, he said for the next sixteen years the appendix was treated as a mere vestige. But in 1904 Macewen raised doubts as to this and reported a case in which a portion of the abdominal wall had been accidentally removed as well as of the cecum, the orifice of the appendix being exposed. Referring then to Weir's first appendicostomy, he asked what inference was to be drawn, and replied that when about to remove an appendix the surgeon should ask himself whether in that particular case it might possibly be wiser to retain it. He went on to show that this could in properly selected cases be done by transferring the appendix from the peritoneal cavity and embedding it in the abdominal wall, opening or excising its distal end, if there was any narrowing. Thus, instead of a mere appendicostomy in which all but a stump of the organ is cut off, the whole or the greater part is preserved. In selecting a case for such a procedure a fair length of the proximal part of the organ must be free from kink, stricture, ulceration, and perforation. Of course, tubercles or actinomycosis were contraindications. Most of the appendix should be placed beneath the fat on the external oblique muscle. Care must be taken not to injure the artery.

The surgical treatment of chronic constipation was also treated in the lecture. Mr. Keetley did not think much of ileo-sigmoidostomy and ridiculed the notion that the cecum was a cesspool. It was, he said, a bag of living tissue with an aperture of egress nearly equal to its own diameter, with a lining of secreting and absorbing epithelium as well as a muscular wall. It was compressed by the muscles of the abdominal parietes and as a general rule contained gas—not feces. In his own practice the lecturer had performed appendicostomy for chronic constipation in nine cases and in all the operation had answered its purpose. It was a clean operation, if properly performed, did not give egress to feces, and did not require a catheter to be kept in.

Sir Dyce Duckworth gave an address on nursing last week at the Institute of Hygiene. He spoke of the progress of the last thirty years and said nursing was seen at its best in the British empire, for the needs of the patients were imperfectly met on the Continent and in the United States. The nurses were rather overtrained. No room in a house, he said, was too good to be ill in, and as the Spanish proverb teaches, "Where the sun comes not the doctor does." He held that our open fire and open window surpassed any "system" of ventilation. The fire could be replenished noiselessly if the fuel was wrapped in paper. As to feeding, he declared it was hard to improve on nature, so he had not much to say in favor of predigested or peptonized foods, which he thought were too often resorted to. Sleep was most important and a well-fed brain sleeps well, but improper food and excessive fluids often prevent sleep. The introduction of the motor traffic has proved a grave danger to the peace and rest of both the healthy and the sick. The tendency of the times is to induce impatience and captiousness, frequently shown by the sick to their medical advisers. A little more stillness and meditation was much wanted in these days.

The reopening of the alcohol question by the manifesto, as I wrote some weeks ago, has aroused the dealers to fresh advertisement and now their recognized organ is distributing a circular in which that document is quoted, together with some still less defensible assertions. But the other side is not idle and a recent volume by Sir V. Horsley, F.R.S., and Mary D. Sturge, M.D., entitled "Alcohol and the Human Body," deals with the subject in a manner that will interest the public as well as the profession, and is especially deserving the attention of politicians. In relation to the public health there is a chapter by Dr. Arthur Newsholme which sums up this part of the question in the fewest words. Of course, scientific statements put forward by Sir Victor Horsley are beyond contradiction and anyone disposed to question his conclusions had need arm himself with something more than prejudice. To how great an extent alcoholism is a disease is not recognized by politicians and reformers, but their eyes should be opened by this accumulation of reliable evidence.

Sir J. Crichton Browne addressed the Bread and Food Reform League at the Mansion House on Wednesday. The object of the meeting was to inaugurate an educational campaign on the diet and health of children. He repudiated any vegetarian tendency and was a firm believer in the value of the mutton chop.* To create a group of mixed hooligans and imbeciles it was only necessary, he said, to starve young children from time to time and diligently ply them with what was called "a liberal education." He would like to see adulterators of food electrocuted.

Mr. Rider Haggard distributed the prizes at St. Thomas' Hospital and told the unsuccessful students not to be downhearted. It was not given to everyone to shine in examinations. This was a self-satisfied world, but we had not rid ourselves of all superstitions when such things as Christian Science, the faith of the Peculiar People, and of the antivaccinationists and those who believed in patent medicines still flourished. One thing they would have to grapple with in future was overcrowding in large cities. The shrinkage of the birth rate would make it necessary for medical men to concentrate their skill and ability upon saving such children as came into the world and preventing the frightful waste of child life. He recommended them to cultivate imagination and go in for hard, steady work.

Dr. Edward H. Bennett of Dublin died on the 21st inst. at the age of seventy. Educated at Trinity College, he graduated A.B., M.B., M.Ch. in 1859, and M.D. in 1864, taking the F.R.C.S.I. the previous year. He was appointed university anatomist and later professor of surgery. He was also surgeon to Sir P. Dun's Hospital, consulting surgeon to Steeven's Hospital, St. Mark's Ophthalmic and the Dental Hospitals, Dublin. He became president of the R. W. A. Surg. in 1884 and was president of the Academy of Medicine from 1897 to 1900, in which year he received the honorary Fellowship of the English College. He represented the University of Dublin in the General Medical Council. He contributed to the *Dublin Quarterly Journal of Medicine* on foreign bodies in the larynx, on ankylosis of the hip-joint, fractures of costal cartilages, etc. On bones and fractures, indeed, his authority was second to none. Anything relating to joints or osseous pathology was intensely interesting to him. The Museum of Trinity College is rich with his specimens. "Bennett's fracture" has found its way into the text books. I believe he was the first to practice Listerism in Dublin. As a teacher and hospital surgeon he was a great favorite with both students and patients.

OUR PARIS LETTER.

(From Our Special Correspondent.)

THE TREATMENT OF TETANUS—APPENDICULAR PELVIC ABSCESS—OYSTERS—TOXICITY OF THE URINE IN APPENDICITIS—ANEURYSM OF THE AORTA—RECTAL EXAMINATIONS—NECROLOGY.

PARIS, June 5, 1907.

AN interesting discussion on the treatment of tetanus took place in the Société de Chirurgie in connection with the presentation of a patient by M. Guinard. Monod spoke of the important work done by Nocard on this disease and stated that it was through this that the efficacy of antitetanic serum had been shown on animals. Pierre Delbet expressed a doubt that the serum acts on man as it does on animals and said that the serum was without action on the tetanus bacillus, as it was simply antitoxic. The serum does not prevent the bacillus from growing, but it does prevent the action of the toxins on the nervous system. The immunity that it confers is only of short duration and some experimenters believe that it does not last longer than ten days. When the serum has been injected into a patient he is immunized against the tetanus toxin for about ten days, but during this period the bacillus either disappears or when the period of immunity is over it may regain its activity and continue to produce toxins, so that the disease resumes its course as before. Therefore the instances in which the symptoms of tetanus appear ten days or more after the injection of the serum prove nothing against the value of the latter. They simply show that its action is of short duration. Delbet said that, far from believing that the prophylactic use of the serum should be abandoned, he was of the opinion that it should be resorted to more frequently. The injections should be repeated at intervals of about ten days until the suspected wound was completely cicatrized. Paul Thiéry and Routier spoke of the distinction that should be made between the use of the serum when the tetanus has already begun and its employment as a prophylactic measure. Under the former conditions it has little or no value, but in the latter case it is certainly effective and its use is entirely without danger. Nearly all the other speakers were of the same opinion and counseled the prophylactic use of the serum.

Pelvic abscess of appendicular origin was another subject that led to an animated discussion before the Société. Picqué spoke in favor of draining abscesses of this sort through the perineum instead of through a rectal incision. He considered that the perineal operation was founded on correct anatomical principles and was well adapted for the drainage of the pelvic peritoneal cul-de-sac, which was rendered easily accessible through its distention with exudate. Routier, on the other hand, was of the opinion that appendicular pelvic abscesses may more advantageously be opened through the rectum, since the operation is easier and recovery is quicker than when the pre-rectal incision is used. Broca also held this view and said that he had never seen any untoward results through secondary infection of the cavity communicating with the rectum. Reynieret and Le Dentu expressed themselves similarly. Mauclaire held that a great deal depended on the situation of the suppurating focus and the direction in which it was pointing. He was not an advocate of exclusive pelvic drainage, but maintained that the abdominal route, the pre-rectal route, and the rectal operation all had their indications and might even be used in combination.

A noteworthy communication on the dangers attending the ingestion of oysters was presented by Netter before the Académie de Médecine. Numerous regrettable instances of gastrointestinal disorders and even of typhoid fever following the consumption of oysters from polluted waters have occurred and have justified the interest taken by the Académie in this question. The only method of preventing such occurrences is to safeguard the consumers from all oysters that have not been protected from contamination. In order to do this the oysters must be gathered only from waters in which there is no possibility of direct or indirect pollution with sewage, and to prevent any subsequent contamination during the transit from the point of origin to the table of the consumer. The Académie adopted a resolution recommending that an investigation should be instituted by the maritime authorities regarding the topographical, chemical, and bacteriological aspects of this question. Only those oyster beds should be used the safety of which has been established by searching investigation, and in which the necessary surveillance recommended by the commission is carried out. All oyster beds should be subjected to regular inspection.

Lannelongue read a paper on the importance of investigating the toxicity of the urine in appendicitis. In acute appendicitis the most careful study of the subjective and objective symptoms is not sufficient to enable even the most skillful clinician to determine the intensity of the infection and to formulate the indications regarding the advisability or nonadvisability of operation. Lannelongue thinks that the problem may be solved by determining the toxicity of the patient's urine. Normally the toxicity is 84 c.c., that is, this quantity of urine per kilogram of body weight must be used in order to kill a rabbit by intravenous injection. The urine of patients with acute appendicitis is three, four, or even five times as toxic as this. When the toxicity is 25 c.c. instead of 84, the patient's death is inevitable unless an operation is done. By means of this method the prognosis may be more accurately determined and by gauging the degree of infection the most favorable time for operation in chronic cases may be selected with great precision. In this connection Hayem observed that it was difficult to compare the toxicity of the urine of appendicitis patients and normal individuals. During the disease the amount of urine was much diminished and its concentration was increased so that its toxicity was apparently heightened. Before injecting the urine it should be made isotonic with normal urine or at least be brought to the same specific gravity.

At the meeting of the Société Médicale des Hôpitaux Lamy and Cléret showed a very large aneurysm of the thoracic aorta which had been almost completely cured by concentric lamination of the sac. The patient was a man of sixty-five years, who contracted syphilis at the age of forty and had spent the last five years of his life in the hospital. The treatment had consisted in rest and the administration of iodide of potassium.

Lion and Bensaude demonstrated a rectoscope intended for examination of the rectum and colon. The use of the high-tension electric current was recommended by these speakers to reduce the pain sometimes attending the use of the instrument. By allowing the current to pass for from four to six minutes almost complete anesthesia is obtained and the instrument may be introduced without causing any discomfort.

Prof. Charrin has died at the early age of fifty years. He was attending physician to the hospitals, adjunct professor

of medicine, member of the committee of hygiene, and professor of pathology in the Collège de France. He did important work in bacteriology and did much to prove the part played by bacterial toxins in infectious diseases. He was also one of the first to introduce vaccination by means of soluble products, and contributed important observations on the bactericidal properties of the blood. His researches on glanders and on the *Bacillus pyocyaneus* enabled him to demonstrate the experimental polymorphism of bacteria. He was taken from the world of science while still in the plenitude of his powers.

Progress of Medical Science.

New York Medical Journal, July 6, 1907.

Auscultation Ratios in Pulmonary Tuberculosis.—J. R. Billings, Jr., mentions the difficulty of definite diagnosis in very incipient cases, particularly those in which these abnormal signs are localized at the right apex and appear to be, qualitatively, but an exaggeration of the normal differences in that area. He noted that in a number of cases, in which abnormal signs seemed to be due to physiological intensification only, there was a corresponding intensification of the signs over the lower part of the right upper lobe, both in front and behind. The breath sounds and vocal resonance, not only of the two sides of the chest, but also of the upper and lower portion of the affected lobe, were always compared. Eventually, by reason of training and experience, he came to feel that he could estimate the relative intensity of the sounds at the apex and lower portion, respectively, of the affected lobe. The results of this continued observation along the foregoing lines are expressed in the following propositions: (1) It seems probable that the relative intensity of the breath and voice sounds over the upper and lower portions of the upper right lobe of the lungs remains about the same in health, being about 5 to 4, or 5 to 3. (2) That when the sounds at the apex are physiologically intensified, there is a corresponding intensification of the sounds over the rest of the upper lobe, the ratio being about the same as in normal chests, namely, 5 to 4, or 5 to 3. (3) In incipient tuberculosis, with beginning infiltration of the right apex, the signs at the apex are intensified, while those over the rest of the right upper lobe remain normal. The ratio between them is thus distinctly increased to 2 to 1, or even higher. (4) An increase in these ratios to 2 to 1, or over, suggests the presence of infiltration, possibly tuberculous, at the apex of the right lung. The author describes certain modifications of the stethoscope which have proven of service in his investigations.

Recognition and Treatment of Pneumonia in Infants and Young Children.—W. P. Northrup says that the early manifestations of pneumonia in infants are sudden onset, prostration, fever, disturbed respiration, altered pulse ratio, and râles. These are sufficient for a diagnosis. Then follow in due order diminished respiratory murmur, bronchovesicular respiration, bronchial voice, and breathing, bronchial "whiff," dullness, and cough. This order he regards as characteristic of practical value and relative appearance. Treatment should commence with castor oil and calomel, or the former alone in full dose. Careful feeding will prevent flatulency. Water internally and externally should be freely used. Fresh, flowing, cool air should enter the sick room freely. Antipyretics may be given, with sponging, but no coal tar products are allowable. For cardiac stimulants we should use wine, whiskey, and strychnine. Complications should be recognized early and treated according to indications. Our great aim is to aid the child in its struggle against toxemia. Poultices are good only for local pain. They should be applied to local areas only, not bound around the chest, and should be used only intermittently. Periods of three hours should be allowed for sleep, during which the child must not be disturbed. The feet should be kept as warm as the head. The author repeats his well known views as to the value of outdoor open air day and night.

A Pathognomonic Eye Symptom in Rabies.—While engaged in studies on rabies W. B. Coakley noticed a peculiar scum which partially covered the left eye of a mad fox terrier dog. On wiping away this discharge he found the pupil in pin point contraction and uninfluenced by light, the cornea and conjunctiva were analgesic, and the outer layers of the former were destroyed. This animal was just entering upon the last stage of the disease and was still strong and very furious. After applying atropine at intervals of ten minutes for one hour, he failed to influence the contraction. Cocaine was then tried with the same result. He then administered large doses of atropine hypodermatically with negative results. After a wait of four hours he gave a large hypodermic injection of cocaine; the result was the same as before. At the end of eight hours after his original observation, the contracted pupil suddenly dilated to about the size of a large match head, while the pupil of the right eye remained practically unaffected. The animal at this time was very weak and unable to stand. His respiration was labored, and the heart sounds were indistinct. Two hours and thirty-five minutes from this time he died. The post-mortem findings were about the same as those usually found in a rabid dog. The same phenomenon was noted in subsequent observations with such constancy as to lead the author to believe it pathognomonic of rabies. It must not be confounded with the pupillary contraction which sometimes follow the sudden removal of an animal from a dark cage to a bright light. If there is any doubt as to the permanency of the contraction, mydriatics should at once be used; if mydriasis is secured and the animal lives for several hours, we may be sure we are not dealing with rabies.

Histogenesis of Tumors, Particularly of Cancer.—The paper of H. Oertel is largely a review of recent literature on the general subject of malignant neoplasms. His own contribution to the matter mainly concerns deductions from a certain case of liver cancer in which he traces the gradual metamorphosis of degenerated liver cells into cancer cells. In this cellular transformation he has detected three transitorial stages. The first one, the destructive stage, is represented by a cell of the type of the liver cell with extensive loss and granular degeneration of protoplasm. The nucleus has lost its structural chromatic arrangement and most of it has disappeared. There remains the form of a vesicle with little or no central chromatin, no distinct nucleolus and at the periphery small, rather faint, apparently unconnected chromatin granules. In the second or incipient regenerative stage the nucleus shows marked enlargement with irregular production of small chromatic granules within the vesicle of the same type as in stage 1, but without definite arrangement or connection. A faint nucleolus may be visible. The protoplasm around such nuclei is still of the degenerated, granular type, and much wasted. In the third stage, finally, these chromatin granules have largely coalesced to form one or more larger rich clumps which are connected; a pale nucleolus is distinct. At this point an accumulation of smooth protoplasm takes place around the very large nucleus, stamping the cell at once as an entirely different type of cell. This is the true cancer stage. A new cell type, identical with the cancer cells, is thus formed directly from the degenerated, wasting liver cells, bridged over only by a small mass of remaining nuclear chromatin. But these cells still enter into the construction of the lobule, and show the arrangement in rows after their individual change in cell character has occurred, and no disturbance of the lobule has taken place; ample proof that these small islands are not metastases, but primary cancerous foci. However, as soon as these new cells begin to reproduce, they break with the former physiological arrangement and structure. As they have lost the morphological character as liver cells, they now prove their new functional type by rapid independent growth, with utter disregard to their original source and surroundings. They begin to infiltrate, their true malignant nature is manifest, a carcinomatous growth is established.

Journal of the American Medical Association, July 13, 1907.

Metastatic Conjunctivitis in Gonorrhea.—J. J. Carroll, after some historical preliminary remarks, reports two cases of metastatic gonorrheal conjunctivitis and discusses the symptoms, diagnosis, and theories of the disease. Its essential distinguishing characteristics are: The primary gonorrheal infection, its bilaterality, the absence (almost invariable) of gonococci in the eye, the generally associated arthritis, the tendency to recurrences and to be accompanied by iritis or iridocyclitis. The diagnosis is rarely difficult, though the ocular conditions alone may sometimes be insufficient to distinguish it from catarrhal conjunctivitis. After iritis has developed and the conjunctival symptoms have become less marked, it may not always be easy to decide which was the primary condition. All the reported cases have occurred in males; whether this is due to anything in the anatomy of the male urethra or not is difficult to say. The most tenable theory of the disease, in Carroll's opinion, is that of a special toxin, and he refers to the results of Morax and Elmassian who produced conjunctivitis with filtered cultures of gonococci which they attributed to the action of the derived toxin.

Lacrymal Obstructions.—M. D. Stevenson describes the methods of treatment of lacrymal obstructions, urging, in the main, conservatism as regards probing methods.

The tendency at present is toward the greater use of the syringe, giving the probe a less active part in the treatment of these cases. The portion of the nose into which the nasal duct enters should be carefully examined before treatment is commenced, especially before passing probes or otherwise using radical treatment, and the treatment of the lower portion should also be gentle. The sac should be extirpated when pus or mucopus can be pressed out and the disease does not yield to conservative treatment, especially in persons who are exposed to injuries, such as stonecutters, farmers, etc. It should also be removed when the disease is bilateral, and if one eye has been lost by hypopyon ulcer the sac should be removed on the side of the healthy eye. He would also remove it in cases of severe ulceration of the cornea with dacryocystitis and as a preliminary to the operations requiring the opening of the eyeball when dacryocystitis is present; in chronic lacrymal obstruction, when normal drainage cannot be restored; when lacrymal fistula is present; when there is necrosis or disease of the bony walls of the canal; in some cases of polypus, or when there is much thickening of the sac lining; in debilitated or nervous persons, or in those who cannot endure probing, and in dangerous conditions, such as tuberculosis or malignant disease. A dilated or atonic sac should often be removed, especially in long standing cases with partial destruction of the walls of the sac and duct. He does not favor the removal of the gland ordinarily, as the flow of tears may be required to remove irritants, etc.

Abdominal Symptoms of Thoracic Disease.—A. A. Jones calls attention to the abdominal symptoms of thoracic disease; the pain referred to the hypochondrium in acute pleurisy, the pains felt not only in the epigastric and hypochondriac regions, but somctimes in the inguinal region in pneumonia, and the striking abdominal symptoms attending empyemas. All these may occur while the physical signs of the thoracic disorder are in abeyance, and he gives an account of one case in which the patient was operated on for appendicitis, and of another in which an operation for perinephritic abscess had been decided on before the real disorder was diagnosed. The explanation of this transferrence of pain to the abdomen is clear when we recall the anatomy of the six lower intercostal nerves, branches of which are supplied to the abdominal parietes. The very troublesome abdominal tympanites of lobar pneumonia is noticed. This usually occurs in patients near the extremes of life or in obese objects with low resistance and myocardial disease. In its most aggravated form it is of bad prognosis and its treatment is eminently unsatisfactory. Usually only strychnia, fresh air, and eliminatives are effective, but in a few cases he has found physostigmin salicylate, 1/100 grain, hypodermically, of some apparent use. One of the most common abdominal symptoms of cardiac disease is epigastric pain, and two cases of myocardial degeneration and rupture are reported. Similar symptoms may occur with angina pectoris, the gastric symptoms yielding to iodides and nitroglycerin. Some so-called cases of gastralgia are due to cardiovascular disease and are relieved by iodides and nitrites. Doubtless aortitis is the fundamental cause in some of these cases, as the pain caused by thoracic aortitis may be felt in the epigastrium. Gastric symptoms are also observed in many cases of valvular heart disease, due, it may be, to passive hepatic congestion or portal or mesenteric engorgement. Whatever the explanation, they yield only to measures that better cardiac action and improve the condition of the circulation generally. Other conditions in the thorax mentioned as accompanied by abdominal symptoms are asthma and emphysema, with or without chronic bronchitis, and the well-known ascites and edema of cardiac disease.

The Acid Intoxication Theory.—Otto Folin reviews the history of the acid intoxication theory, which he does not think will suffer materially from the more recent findings. He especially notices the work of Knoop as furnishing a working hypothesis defining not only the material out of which the acetone bodies can be formed in diabetes, but also the chemical reactions involved in their formation. His fatty acid oxidation theory admirably accounts for the facts and it gives a tangible conception of the intermediary catabolism involved in the oxidation of foods in the animal organism. By linking the fatty acids to the stable benzene group Knoop was able to arrest their otherwise too rapid oxidation at enough intermediate points to form a fairly definite conception of the successive steps in their destruction. Summarizing the results as regards normal fatty acids, we may say that all these which contain an even number, and not less than four carbon atoms, can be oxidized to oxybutyric acid. Normal fatty acids which contain an odd number of carbon atoms cannot yield oxybutyric acid. The formation of oxybutyric and diacetic acid in these cases may be said to be due to the fact that the diabetic organism is not able quite to finish the attack of the betacarbon atom of butyric acid. Whether this is a matter of faulty oxidation or of inadequate hydrolysis Folin considers still uncertain. The amino acids which go to make up the proteids may by parting with their amino groups become fatty acids and thus also the precursors of the acetone bodies. The question whether fat or protein is the chief source of the acetone bodies is, theoretically, at least, settled. There are still things uncertain and calling for further investigation in these recent researches, and some important questions calling for discussion, but Folin passes to the question of the alkaline therapy of acidosis which must after all furnish the final proof of the acid intoxication theory. He criticises the dependence on sodic carbonate alone as not in accordance with current physiologic teaching, and this may serve to explain its shortcomings. The superiority of salt mixtures as against any one salt in maintaining living tissues intact has been abundantly demonstrated, and flooding of a diabetic patient with sodium, considering the toxicity of some of its compounds, may be injurious or less helpful than the use of an equivalent mixture of sodium, calcium, potassium and magnesium. Since the blood of these patients shows a diminished capacity for carrying carbon dioxide, he thinks the useless and burdensome carbonic acid of the carbonates should be replaced by organic acids having some fuel value. Like other foods, they ought to reach every part of the tissues as the precursors of oxybutyric acid are supposed to do, and through their oxidation the oxybutyric formation should tend to decrease, and whatever did form be neutralized in the very cells where it originates, a result confessedly lacking in the sodium carbonate treatment.

The Lancet, June 29, 1907.

The Influence of School Life on the Spread of Scarlet Fever.—That schools greatly contribute to the spread of scarlet fever is the view of B. K. Goldsmith, one of the health officers of Manchester. He presents elaborate tables and a chart showing local conditions in reference to his main contention. His study embraces 19,219 cases. In taking up the question of school influence, we may ascertain the day of the week on which the onset of each case occurs. By this method one can see on which day most cases arise, and further, whether Saturday and Sunday, days of non-attendance at school, produce any influence in lessening the number of cases on certain days following, allowance being made for incubation. Again comparison can be made between the holidays and the school terms in relation to the days of onset. It is of importance also to ascertain if, as regards the day of the week, the onset in infants and adults corresponds or not with the results obtained in school children. A second method of approaching the subject consists in ascertaining the total number of cases occurring among children of school age during the holiday and comparing this with the number of cases occurring during an equal period of time before and after the holiday. Further, the effects of the holidays on infants and adults must be compared with that in children of school age. One might expect infants to show only a slight diminished incidence during the holidays. In adults also a fall may be expected, proportionately greater, however, than in infants, owing to the diminished number of cases among school children during the holidays. This fact, of course, would tend to lessen the number of cases in infants also, but the greater amount of contact during the holidays between infants and those members of the family who are of school age will in all probability counterbalance the diminished prevalence of scarlet fever among the latter. In adults the amount of contact is not increased, as they are at work all day and are exposed to infection from school children mainly in the evening whether the schools are open or not; this observation refers chiefly to male adults, but it is applicable in a less degree perhaps to females also, many of whom are employed in mills, shops, etc. The author's cases extend over a period of nine years and his tables, while they cannot be well abstracted, are yet very suggestive to educational officers. Most striking is the sudden rise in the number of cases when the schools reopened after summer and Christmas holidays. The author simply presents his facts without suggestions as to remedying the present state of affairs, except as to hint at the systematic medical inspection of all school children and the instruction of teachers in the recognition of the early evidences of the contagious diseases.

Rice and Beri-Beri.—W. Fletcher presents a preliminary report on experiments conducted in the lunatic asylum in the Malay States. He declares that uncooked rice is either directly or indirectly a cause of beri-beri, the actual cause being either (1) a poison contained in the rice; (2) deficiency of proteid matter, the disease being due to nitrogen starvation; or (3) uncured rice does not form a sufficiently nutritive diet and renders the patient's

system specially liable to invasion by a specific organism, which is the cause of beri-beri. The author excluded all doubtful cases from his statistics. Examination was made of the knee-jerks and of the presence or absence of edema. Comparisons were also made on the basis of rice grown in different localities. Thus on a given day the figures were as follows: the knee-jerks of patients on Siam rice, present, 13; absent, 18 (in 5 absent on admission); increased, 6; total, 37. Knee-jerks of patients on Bengal rice, present, 23; absent, 8 (in each case absent on admission); increased, 5; total, 36. With regard to edema, patients on Siamese rice 10 out of 37 had it and patients on Bengal rice 4 out of 36. Sixteen of the 37 patients on Siamese rice had been on this diet for a considerable period; in 8 of these 16 cases the knee-jerk was absent and in three it was increased, while in five edema was present. In all those 8 cases on Bengal rice in which the knee-jerks were absent they were noted as being absent on admission. Three were cases which had been transferred to a Bengal rice diet after having developed beri-beri while on a Siam rice diet. Two had been treated for beri-beri in other hospitals. Two gave a history of previous attacks. In one case the cause of absence of reflex is unknown. Since the end of December, 1906, up to the present date (May 10, 1907) 12 cases of beri-beri have developed among the patients on a Siamese uncured rice diet. No patients on Bengal (cured) rice have suffered from the disease. Thus excluding patients actually suffering from the disease on their admission to the asylum, there were 51 cases of beri-beri among the patients on Siamese rice and none among those on a Bengal rice diet.

Loss of the Tendo Achillis Reflex and Its Diagnostic Value in "Alcoholic" Failure of the Heart.—R. T. Williamson recognizes a clinical form of heart disease due to the ingestion of large quantities of beer or spirits. It may be that the exact cause of the affection is the alcohol itself or some impurity, as arsenic, which has been known to be in beer in sufficient amount as to cause an epidemic of peripheral neuritis. The author notes that loss of the tendo Achillis reflex is one of the first signs of the injurious action of alcoholic beverages on the peripheral nervous system and this reflex is often lost before the knee-jerk. His investigations demonstrate that in cases of heart disease not due to alcoholism, the tendo Achillis jerks were present in all cases except two, and in those two cases the loss of these reflexes was almost certainly due to early tabes. On the other hand, in *alcoholic* heart failure the tendo Achillis jerks were lost on both sides in sixteen out of twenty-one cases, on one side in two other cases; they were both present in only three cases. In these three cases the symptoms were slight and the diagnosis not quite certain. Hence we may say that the tendo Achillis jerks are present in non-alcoholic heart disease unless there is some nervous complication, but are usually absent in alcoholic heart failure if the symptoms are well marked and if edema and dyspnea are both present (*i.e.* absent in alcoholic heart failure on both sides in seventy-six per cent. of cases, on one or both sides in eighty-five per cent.). The loss of the tendo Achillis jerks in alcoholic heart failure is probably due to very early neuritis. It is not due to the edema of the leg, since these reflexes may be obtained in non-alcoholic cases when there is marked edema. The author thinks, therefore, that under certain conditions the tendo Achillis may be of service in the differential diagnosis of alcoholic heart failure, but we should first exclude diabetes mellitus, diphtheria, and tabes as causes of the loss of the tendo Achillis jerks. Providing there is no glycosuria, no evidence of a recent attack of diphtheria, no sign of lesion of the spinal cord, or cauda equina, and providing the pupils react to light and that there are no lightning pains or other signs of tabes dorsalis, then the loss of the tendo Achillis jerk is of value in diagnosis as a confirmatory sign that the alcoholic beverages taken have had an injurious action on the system—*i.e.* that they have produced one of the first signs of their toxic action on the peripheral nerves.

British Medical Journal, June 20, 1907.

Relapses in Enteric Fever.—The case reported by H. C. Hamilton concerns a girl of sixteen years who was admitted to hospital at about the end of the third week of typhoid. At the end of five days her temperature had fallen to normal. She had had during this time two slight hemorrhages, but seemed on the way to convalescence. In twenty-four hours, however, the temperature began to rise and for the next ten days it varied from 99 to 102°. It then dropped suddenly 3°, unaccompanied by any other immediate symptom or sign. She died four days later. Autopsy showed non purulent peritonitis and a small perforation six inches above the ileocecal valve. The author notes as a feature of the case the fact that care proved fatal in a relapse, which is contrary to rule. When such fatality results it is nearly always due to some such complication as that mentioned above, partial immunization having almost certainly exempted the patient from the effects of a toxemia sufficient to cause death. The case also exemplifies the difficulties which are sometimes present in the diagnosis of perforation, even in the absence of abdominal distention and where the patient is quite conscious. There was no acute sudden pain, no marked collapse, no great or immediate alteration in the pulse. In fact, there was practically no evidence which would justify the immediate diagnosis of a perforation.

Surgical Tuberculosis and the Opsonic Index.—Two cases are reported by J. Stark illustrating the infection of the blood system in surgical cases of tuberculosis. In the first case a child (male), aged two years, had an attack of acute ascites, put down as tuberculous in origin, although there were no enlarged glands to be found. The child made a good recovery, but about a year afterwards it came again under his care, suffering from tuberculous periostitis of a rib with abscess. He advised surgical interference. The rib was scraped and a tuberculous necrosis removed. The wound healed nicely, but the child developed tuberculous meningitis, and died about five weeks later. The second case was one of tuberculous knee. Excision of the joint was performed, and the child recovered from the operation, but showed symptoms of meningitis four weeks later, and died of that condition about one year later. These two cases tend to prove that there is a great danger of general infection by interfering with localized tuberculosis, and also that tuberculous meningitis, bone lesions, and peritonitis are caused by the same bacillus—namely, the *typus bovinus*. That children are more susceptible to bovine tuberculosis is shown by the preponderance of bone, meningeal, and abdominal lesions in children as compared with adults.

Severe Hemoptysis Treated by Means of Ice Bags.—H. Downes reports one case, his patient being a man of twenty-eight years. The author's object in reporting it is to call attention to the value of a therapeutic measure which has fallen into unjustifiable disuse. The treatment in this particular instance included absolute rest with the shoulders slightly raised, a diet of milk and eggs, and mild saline aperients. Hypodermic injections of morphine (one-quarter grain) were given at first, but were discontinued as ineffectual. Amyl nitrite was administered in 3-minim capsules at frequent intervals, but appeared to have no effect. Finally an ice bag was applied over the front of the right upper lobe, and kept continuously in position night and day, the ice being frequently changed. Not a single drop of blood was expectorated from the time it was first applied. All drugs were stopped and the bag kept in place for six days. At the end of that period the chest was examined, and no crepitations could be discovered. The patient is now (twelve weeks after the cessation of the attack) rapidly improving in health, has gained fifteen pounds in weight, and has no cough or expectoration. The author notes that it is seldom that the bleeding point can be localized with sufficient accuracy for the ice to be applied directly over the seat of the hemorrhage, and thus to produce reflex contraction of the pulmonary vessels in the affected lobule. If applied in the wrong place, it probably does harm by raising the blood pressure in the region of the hemorrhage. In the case under consideration there is little doubt that the blood was coming from a minute cavity situated deeply in the lower portion of the right upper lobe, since there was no sign of breaking down of lung tissue in any other situation.

Goiter Operations Under Local Anesthesia.—Local anesthesia in cases of goiter operation is commended by A. J. Fairlie Clarke, who has had very satisfactory results therewith. He follows the general plan previously advocated by Barker and uses the following solution: sodium chloride, 12 grains; beta eucaine, 3 grains; water, 3½ oz.; this is boiled, and then 10 minims of commercial adrenalin solution are added. The solution is ready for injection as soon as cool enough. The injection is made in two parts, superficial and deep. The superficial injection is made about the middle of the line of the proposed operation wound with a long, sharp needle; by passing the needle through the subcutaneous tissue and injecting at different points, the whole site of the incision can be dealt with through a single puncture. It is well to inject high up and to the outer side of the incision line, so that the nerves may be dulled on the proximal side of the wound. Half of the 3½ oz. of fluid are injected superficially. For the success of the deep injection it is important to introduce the fluid behind the transverse layer of the cervical fascia, so that it may reach the nerves which compose the cervical plexus. To this end the author has been accustomed to make a deep stab puncture with a sharp tenotomy

knife—if possible, through skin already anesthetized, behind the posterior border of the sternomastoid muscle at the junction of its upper with the second fourth. The puncture is made here to be above the point at which the spinal accessory nerve emerges from the muscle. A flexible blunt-pointed steel needle is then passed along the track of the tenotome deeply into the neck, and the remaining half of the fluid injected here. If need be, the process may be carried out on both sides of the neck at once, 3½ oz. of the fluid being injected on each side. The injection, apart from the punctures, does not seem painful, though some patients complain of fullness in the throat during the deep injections. All this injecting can be done with the patient in bed, and after a brief delay she may be moved to the operating room, where the operation should begin not sooner than half an hour from the commencement of the injection. The anesthesia will last for at least an hour after the commencement of the operation. The edema produced in the tissues is often considerable, but is seldom troublesome to the surgeon, for the bloodlessness of the tissues due to the adrenalin compensates for the inconvenience so caused. The operations done have been excisions of half the thyroid gland or ligature of both superior thyroid arteries. The arteries were found without difficulty.

The Electric Treatment of Lupus Vulgaris.—Three cases are reported by J. G. Tomkinson. Case 1, male, twenty-five years of age, was treated wtih the Finsen light, and Case 2, female, twenty-three years, in a similar way. In Case 3 a woman of twenty-seven years, the Finsen light, iron electrode lamp, and the *x*-rays were all used. Results in the first two cases were very satisfactory, but the third case, after partial improvement, seemed to hang fire. The *x*-ray treatment was alternated with a mildly caustic treatment consisting in the removal of as much of the diseased tissue as possible by the use of a strong salicylic acid plaster, the subsequent application of ichthyol in ointment and lotion till the irritation more or less subsided, and thereafter repeated cauterization by 80 per cent. phenol in absolute alcohol.

Berliner klinische Wochenschrift, June 24, 1907.

Abdominal Extirpation of the Carcinomatous Uterus.—Veit says that while the results of the abdominal operation have shown it to be superior to vaginal hysterectomy as far as results are concerned the latter operation has had the reputation of having a smaller primary mortality. He considers that the abdominal operation has now been perfected to such a degree as to render it just as safe as the other, and he reports twenty-four consecutive cases which he has done without any primary deaths. He believes that this operation may now be considered both theoretically and in practice as a procedure without risk to life. Its dangers are the result of its complications, which are common enough in advanced cases. Among these, injuries to the urinary passages are especially serious and gangrene of the ureter is difficult to manage. Cardiac failure has become less of a menace since the introduction of spinal anesthesia, and the less often general anesthesia is used the better the results. The experience of the surgeon is an important factor, and the results obtained improve in proportion to the operator's familiarity with the operation. The author operates on nearly all cases except those in which there is already a vesicovaginal fistula or in which the new growth fills the entire pelvis.

Münchener medizinische Wochenschrift, June 18, 1907.

The Relations of the Medulla Oblongata to the Pupil.—Bach states that there is an inhibitory center in the medulla for the pupillary reaction which is extremely delicate. Experiments on this center are rendered difficult because it is a very small one and the lesions produced in the medulla either injure it sufficiently to throw it out of function or do not approach it closely enough to influence it at all. By experiments on monkeys, cats, and rabbits the author was able to show that decapitation does not abolish the pupillary reflex unless the medulla is destroyed up to the fourth ventricle. On cutting through the medulla near the spinal end of the ventricle immediate disappearance of the light reflex may be caused, but this is never the case when the incision is placed a little to the cerebral or the spinal side of this spot. On exposing the fourth ventricle from the rear myosis and loss or diminution in the light reflex was observed, and in some instances the reflex was caused to reappear after the lapse of as much as three-quarters of an hour by making an incision to the cerebral side of the middle of the ventricle.

The Use of Scopolamine in Obstetrics.—Holzbach has investigated the question of the excretion of scopolamine as used by injection in obstetric practice. The most serviceable method of testing the milk and urine of the mothers and the urine of the infants was found to be the physiological test on the enucleated frog's eye. Tests on thirty-five eyes showed that the colostrum of the parturient women always gave a dilatation of the pupil, and the milk did the same up to the third day postpartum. The urine of the infants obtained immediately after birth always contained the alkaloid, while the second passage gave a much less marked reaction, and in the third it could usually not be detected at all. Even when the hyoscine had been given only once a quarter of an hour before birth the alkaloid was found present in the urine of the infant. The author accordingly concludes that the hyoscine administered to the mother is not only excreted in the urine, but is also present in small amounts in the colostrum and milk during the first few days. It also passes through the placental circulation into the body of the infant, from which it is promptly eliminated through the kidneys. Whether the child suffers as the result of this is not yet certain, though it seems unlikely. The proof of the presence of small amounts of the alkaloid in the infantile circulation appears, however, to justify the contention of Gauss that the respiratory difficulties often exhibited by children born under scopolamine anesthesia are referable to this cause.

Deutsche medizinische Wochenschrift, June 20, 1907.

A Contribution of the Subject of Myontonia Congenita or Thomsen's Disease.—Kamp was called to see a young man suffering from this condition and on investigation found that the disease had been hereditary in his family for four generations. A peculiar coincidence was that two members of two entirely unrelated families, both suffering from Thomsen's disease, married and were among the patient's antecedents. The disease had been transmitted both through sons and daughters, but the tendency to it subsides more quickly on the male side than on the female. When the disease has died out in one branch of the family it does not appear again in the descendants of that branch. In the author's case the principal causes for the occurrence of the muscular cramps were cold, psychical excitement, mechanical stimulation, and the sense of hunger. The tendency to the attacks was decreased by warmth and by the ingestion of alcohol. There appeared to be neither muscular atrophy nor hypertrophy in the patient or his relatives.

A Simple Method of Performing the Agglutination Reaction.—Gossner describes a method for performing agglutination tests, particularly that for typhoid fever, which has been simplified to such a degree as to make it easy to carry out under all circumstances and without any bacteriological training. Whole blood is used and is diluted with formalin salt solution by the addition of the necessary number of drops of diluting fluid to the drop of blood. The bacteria used are in the form of a sterile formalin culture and are added to the blood dilutions in small test tubes. The essential part of the method consists in the fact that after the physician has made the necessary dilutions at the bedside he leaves instructions with the patient's attendant at the lapse of two hours and again at four hours to place a drop of the mixed blood and bacterial culture on ordinary microscopic slides that are labeled beforehand. These drops dry promptly and at the physician's next visit the slides are taken back to his office, fixed, and stained with methylene blue. If agglutination has taken place it is readily discernible with the naked eye on holding the slide to the light, and if desired the result may be confirmed by the use of the microscope. The advantages of the method are the simplicity of the apparatus required, the fact that no dangerous material is used, and the slight degree of trouble it involves for the busy practitioner.

Veratrum Viride in Eclampsia.—F. Mirto gives the histories of sixty-one cases of eclampsia treated by the hypodermic use of extract of veratrum viride in the obstetrical clinics of Pavia and Milan. He recommends the use of this drug because the convulsions are invariably accompanied by a rise in arterial pressure, which may be regarded as an index of the approaching seizure, although it may not be the cause of the convulsions. He has observed that as soon as the arterial pressure is lessened the convulsions are moderated, the frequency of the attacks is lessened, and in some cases the convulsions are so controlled that the pregnancy can go on to full term and delivery be normal. He has also given it as a preventive measure in many cases in which there was albuminuria and casts accompanied by high arterial pressure, and believes that it prevented the convulsions which would otherwise have occurred. He recommends the use of the drug as a preventive and as a curative treatment for frequent and puerperal convulsions.—*Annali di Ostetricia e Ginecologia.*

Book Reviews.

Auscultation and Percussion. together with other Methods of Physical Examination of the Chest. By Samuel Gee, M.D., Fellow of the Royal College of Physicians, Honorary Physician to H.R.H. the Prince of Wales, and Consulting Physician to Saint Bartholomew's Hospital. Fifth Edition. London: Smith, Elder & Company, 1906.

There is very little difference between this edition and the two previous ones. The author has taken great pains with the nomenclature of the subject, and technical terms are used in their proper and original meaning. "The sense of words clearly defined has not been perverted, nor have new words been introduced to denote signs already well denominated." Among the characteristics of this work are the literary and historical notes; also the very careful language and classification employed by the author. To one beginning the study of medicine the work will hardly appeal; but to the practitioner and to all interested in the history of the subject this little volume will prove most valuable and instructive.

The Muscles of the Eye. By Lucien Howe, M.A., M.D., Professor of Ophthalmology, University of Buffalo; Member of the Royal College of Surgeons of England; Member of the Ophthalmologische Gesellschaft, of the Société Française d'Ophthalmologie, and of the Ophthalmological Society of the United Kingdom; former President, Section on Ophthalmology, American Medical Association. In two volumes. Vol. I., Anatomy and Physiology. Including Instruments for Testing and Methods of Measurement. Illustrated. New York and London: G. P. Putnam's Sons, The Knickerbocker Press, 1907.

The first volume of this work is a book of 467 pages, beautifully printed and illustrated. In Part I directions regarding the preservation of tissues and the desired dissections are given very fully. Complete descriptions of the extrinsic ocular muscles, the orbitoocular fascia, the cheek ligaments, and other structures connected with the ocular muscles are found in the first chapter. The second chapter treats of the anatomy of the intraocular muscles and the other parts of the eye concerned in accommodation. A third chapter gives a description of the nerve supply to the muscles and a comprehensive review of our present knowledge of the subject. Short chapters devoted to the vascular supply and to the embryology of the muscles and the ocular group of nerves are included. Part 2 takes up the consideration of the physiology of the eye, and enters quite fully into an explanation of the planes, axes, angles, etc., a knowledge of which is essential to the intelligent study of physiological optics. The act of accommodation is considered in another chapter. The significance of entoptic images, their changes, and the methods of studying them; the theories of the mechanism of accommodation, range of accommodation; irregular contraction of the ciliary muscle; the effect of cycloplegics and mydriatics from personal studies, as well as from those of others; the rapidity of the movements of the eye from one position to another, etc., are discussed. The question of the position of the eyes in relation to each other (orthophoria, heterophoria, etc.) is fully considered; the methods employed in this study are described and their relative values, as estimated by the author, are given. The phenomena of torsion and of "false torsion" are described and the rules governing the latter are formulated. Convergence and the various methods of measuring it are fully discussed. The last chapter is followed by an extensive bibliography, an index of authors and three short appendices. The index is followed by biographic notices of eight eminent students of ocular muscles. The text is as clear and as simple as the author could make it. Very few formulæ are employed, the purpose of the author being to produce a work which one not familiar with higher mathematics could understand. The volume presents the subject in a fairly complete, practical form, and will be welcomed by all who are interested in the study of the muscles of the eye.

Studies in the Bacteriology and Etiology of Oriental Plague. By E. Klein, M.D., F.R.S. Lecturer on Advanced Bacteriology at the Medical School of St. Bartholomew's Hospital, London. With 80 photographs. London and New York: The Macmillan Company, 1906.

The contents of this volume are sufficiently described by the title. The author, well known as an expert in bacteriological work of all kinds, has had unusual opportunities for investigating the bubonic plague both in human beings and in rats. In the present volume will be found accounts of cases which, from the point of view of the clinician and epidemiologist, were under suspicion of being plague; on bacteriological examination some of these cases proved to be plague, and others proved not to be plague. To medical officers of sea ports this book will be indispensable, since it is only by bacteriological examination that the diagnosis of plague can, in all cases, be made with certainty. Health officers in general will find this an instructive volume, for, as the author says, "no greater misfortune, from a public health point of view, could befall a community than an epidemic outbreak of bubonic plague in a large and crowded city."

The Immediate Care of the Injured. By Albert S. Morrow, A.B., M.D., Attending Surgeon to the Workhouse Hospital and to the New York City Home for the Aged and Infirm; Assistant Attending Surgeon to the Manhattan Maternity Hospital. Fully illustrated. Philadelphia and London: W. B. Saunders Company, 1906.

In the present volume the author has endeavored to prepare a book that should prove useful alike to physicians, nurses, and laymen, and at the same time serve as a textbook for use of First Aid classes. It is more than doubtful if any one volume on a technical or scientific subject can be really serviceable to all of these classes; but the author has certainly produced a volume that will be of considerable benefit to laymen and as a text-book for First Aid classes. The first part is on the anatomy and physiology of the human body, and in about one hundred pages the author has managed to compress, with unusual skill, the essentials of the subject. We think this part far superior to many books on Anatomy and Physiology written especially for nurses. The second part deals with bandages, dressings, practical remedies, etc. The volume concludes with chapters on various accidents and emergencies, such as hemorrhage, wounds, burns, fractures, dislocations, asphyxia, unconsciousness, poisoning and its treatment, and the transportation of the injured. These last two parts form the most important and valuable portion of the book, and they include all the emergencies that are likely to occur in even the most enterprising families. The book is well written, the advice it contains is always sound, and the author is to be congratulated on having composed a volume which many practitioners will be glad to recommend to the families under their professional care, and which will be of much value in every household at a distance from a physician.

Anatomical Terminology, with Special Reference to the [B.N.A.]. By Lewellys F. Barker, M.D., Professor of Medicine, Johns Hopkins University; formerly Professor of Anatomy, Rush Medical College, University of Chicago. With Vocabularies in Latin and English and Illustrations. Philadelphia: P. Blakiston's Son & Company, 1907.

This is a presentation of the Basle Anatomical Nomenclature—the [B.N.A.] of the title—which was adopted with the purpose of systematizing and simplifying the nomenclature of anatomy, which in the course of the ages has become confused and divergent in the different countries. The Anatomical Society, meeting at Basle in 1895, made a list of some 4,500 anatomical terms for use by anatomists throughout the world, employing only one Latin designation for each anatomical structure (not microscopical), and doing away with the vast number of synonyms which had grown up in the terminology of this science. The book contains the complete list of the Latin terms adopted by the Anatomical Society, with their English equivalents and their synonyms, and is enriched by a scholarly introduction by Professor Barker, explaining why this nomenclature was adopted and the principles which guided the compilers in their work. Future writers on Anatomy will, without doubt, adopt this nomenclature, and the author of this work has done well in preparing the way for the general adoption of this simplified terminology by publishing the vocabulary of the Basle reformers and explaining its *raison d'être*. In the field of pure anatomical science this is the book of the year.

Dining and Its Amenities. By A Lover of Good Cheer. "He that is of a Merry Heart Hath a Continual Feast." New York: Rebman Company, 1907.

This is a collection of papers read before a club of literary and professional men who dined together once a month and enjoyed a feast of reason as well as of the most delectable of viands. If the chef provided a menu which pleased the palate as much as the essays here collated must have delighted the soul, one may well have envied the select coterie of diners. One might have been satisfied, indeed, with bread and cheese and good old ale accompanied by such charming discourses on gastronomic lore. Most of the essays have to do with alimentation ostensibly, but incidentally nearly every subject of human interest is touched upon. The book will not please the ascetic, but to the man who loves good cheer in his moments of relaxation, the reading of these papers will afford a delightful entertainment

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW JERSEY.

One Hundred and Forty-first Annual Meeting. Held at Long Branch, June 25, 26, and 27, 1907.

(Special Report to the MEDICAL RECORD.)

THE PRESIDENT, DR. ALEXANDER MARCY, JR., OF RIVERTON, IN THE CHAIR.

Tuesday, June 25—First Day.

THE House of Delegates devoted all the morning and part of the afternoon session to hearing the reports of committees.

Addresses of Welcome.—Rev. GEORGE L. DOBBINS of the Methodist Church opened the afternoon session with invocation. Charles O. McFaddin, Mayor of Long Branch, welcomed the Society and tendered the members the freedom of the city during their stay.

It was announced that Senator Jos. Frelinghuysen, the father of the pure food bill in the Legislature, was ill at the Auditorium Hotel, Chicago, and the following telegram was ordered sent: "The Medical Society of New Jersey, in annual meeting assembled, send greetings. We appreciate your services in behalf of scientific medicine and sincerely hope for a speedy restoration to health." Dr. Chandler announced that the membership amounted to 1,230. Over 200 registered at this meeting. A committee was ordered to be appointed whose duty it was to select a subject and make conditions for competition for two prizes, one of $100 cash, the other a medal worth $50.

The Legality of State Medical Examinations and Reciprocity in Interstate Medical Licensure.—Dr. E. L. GODFREY of Camden presented this communication. He said that the legality of State medical examinations and interstate reciprocity in medical licensure had offered occasion for such diverse comments in medical societies and medical journals and the opinions expressed by the profession were so at variance one with another that he ventured to present these subjects for the consideration of the society. Prior to the institution of State examinations for medical licensure, the degree of doctor of medicine was conferred after two courses of lectures of five months each in two calendar years, and by some colleges for a consideration and without attendance upon lectures. The registration of a copy of a medical diploma with the clerk of the county in which he was to reside was the only requisite for legally practising medicine in several States. The State of New Jersey in 1890 instituted examinations as a prerequisite for license to practise medicine within its borders irrespective of medical registration in another State; and in addition requiring the possession of a legitimate medical diploma. The subject of the legality of State medical examinations, especially in New Jersey, was presented from two standpoints: (1) The history of medical legislation in New Jersey, and (2) the right of the State to establish examinations for licensure and to regulate medical practise within its jurisdiction under the authority and constitution of the United States, as interpreted by the United States Supreme Court.

Special Inquiries in Respect to State Medical Examinations.—The following were some of the most frequent inquiries made to the Board: (1) What had State examinations accomplished in New Jersey? History gave its answer. He had no hesitation in stating that New Jersey, in establishing medical examinations in 1890, had done more to protect the public health and to advance the medical profession of the State than by any other enactment since the incorporation of the Medical Society of the State of New Jersey, 117 years ago. (2) What would be the effect of establishing educational licensing boards with lower standards of a limited field of treatment, as proposed in the Legislature last winter? It would prove injurious to the public and detrimental to the profession. (3) What would be the effect of discontinuing the State medical examinations? The State could not guarantee proper qualifications of the medical licentiates. The present high standards for medical graduates could be maintained only through State examinations. (4) Why could not national examinations to license the practitioner be created, either by Federal Government, or through voluntary effort of the American Medical Association, the certification of which would be accepted in lieu of examination by the several States? Neither of these propositions was tenable. The practise of medicine, law, and other professions was conducted under reserve police authority of the States. Over the authority the Federal Government had no control. (5) The plea was frequently advanced that a State certificate earned upon examination should be valid in all States on the ground that the science of medicine was the same everywhere. The theory of this was admitted, but its application was impracticable because of the condition of the medical statutes in the forty-six States. (6) It was claimed that a license issued by a European Government was valid in all the States and provinces belonging to the nation and therefore a license issued by one American State should be valid in all of the United States. There was a marked difference between Europe and America in the issuing of medical licenses. European nations were on a monarchical basis, while the United States was a republic. In England and the Continental nations the regulation of the practice of medicine was the prerogative of a central government; in the United States such regulations were in the provinces of forty-six different State governments. (7) The plea had been advanced that a State should respect the medical school to which it granted a charter, guarantee the validity and scope of its diploma, and endorse the same in lieu of a State examination. A State had no right to inspect a particular medical school except when so authorized by the statutes. The State could not guarantee the validity of a diploma issued by a school which it did not control. The Council on Medical Education of the American Medical Association had inspected 160 medical schools in this country and of these only eighty were found to be qualified to teach medicine and to have the facilities for giving medical instruction.

Reciprocity in Medical Licensure.—He said this had recently been placed before the medical profession in an exaggerated, absurd, and an erroneous light by Dr. William J. Mayo in his presidential address before the American Medical Association at its last meeting. His statement that present conditions of reciprocity were well nigh intolerable was an exaggeration, since about 50 per cent. of the States were exercising reciprocal privileges. Reciprocity was not a compulsory requirement, but a discretionary privilege. It was exercised in the interests both of the public and of the profession and rested upon uniformity in State standards. It promised public good by raising standards. It protected the public by limiting the migration of charlatans. It set a premium upon higher medical education because it was denied to graduates of substandard colleges and licentiates of substandard boards. Dr. Godfrey presented the subject of interstate reciprocity in medical licensure from four standpoints: (1) Its legality; (2) its limitations; (3) its necessity and justice; (4) its method of accomplishment. Its legality and endorsement were natural outgrowths of State examinations. They were based, first, upon the reserve police right of a State to regulate the practise of medicine within its own jurisdiction for the public good; second, in specifying the provisions or power of the statute of a State to establish reciprocal relations with other States, and third, on voluntary agreement between different State boards concerning the conditions and methods of examination. Recip-

rocity must necessarily be limited to States having substantially equal licensing standards. These limitations were, first, difference in requirements of medical colleges in respect to matriculation and graduation; second, inequalities of standards of the several States in respect to licensure; third, diversity in rules of medical boards as to methods of examination and percentages given; fourth, issuing of certificates on other than a State examination basis; fifth, there were a few States that endorsed the license of other States only which in turn endorsed theirs; sixth, some States (as Massachusetts) would not endorse the certificate of any State; seventh, the moral character and professional standing of applicants occasionally limited reciprocity; eighth, the requirements for reciprocity should be substantially the same as those for examination. Its necessity and justice were based upon two factors, one of which was the increased demand for interstate medical licensure. Regarding the method of accomplishment, he gave the requirements of New Jersey as follows: 1. A certificate or evidence of a diploma, which was granted after four years of study in a high school in the first grade in this State, or its equivalent as determined by the State Superintendent of Public Instruction. 2. Certified evidence of a medical diploma issued after four years' course of lectures of at least seven months each in four different calendar years from an approved medical college. 3. A copy of a certificate of a State medical license, showing that the standard of requirement of the issuing State was substantially the same as that of New Jersey. 4. Certified evidence of good moral character. 5. A letter of recommendation from a registered physician of New Jersey. 6. A recently signed photograph of the candidate with an affidavit as to the identity of the signature.

Dr. W. Perry Watson of Jersey City believed that every State should divorce the teaching from licensing power; that it should adopt academic medical requirements, and that it should harmonize the physicians and unite them in the State. The requirements and wishes of the people, too, should be considered. The personnel of those applying last week for medical license was far better than that of those taking the examination ten years ago; they were of a much higher average grade than ten, yes even five, years ago. The Board of Medical Examiners, he believed, should consist of nine members of recognized powers; they should meet three days every year for the examination of candidates; each member of the board should prepare the questions in his branch and submit them to the entire board for final approval before they were handed to the candidates; the examination papers should be left with and graded by a committee of three members, the examiner himself being the chairman of that committee; the final report of such a committee should be reviewed by the entire board acting as a committee and as a whole. After a second rejection candidates should be required to take one full year's course of study. Oral and clinical examinations should be asked for.

Dr. Mortimer Lampson of Jersey City, Dr. W. H. Davis of East Orange, Dr. Baldwin of Newark, Dr. E. E. Worl of Newark, Dr. Campbell of Short Hills, and Dr. Geo. H. Balleray of Paterson discussed this paper.

Some Remarks on the Lymphatics.— Dr. F. M. Z. Hawks of Newark read this paper. He said that the lymphatics concerned each individual cell, and that the intercellular lymphatics received the waste products. Absorption occurred by means of the blood capillaries and lymphatics, the blood capillaries taking up the material by selection. The lymphatic capillaries absorbed the secretions of certain of the ductless glands. The lymphatics were active under pathological conditions. When toxins were introduced into the blood by the lymphatics it was associated with fever and other constitutional symptoms. At first there was a chill and afterwards more or less constitutional disturbances, but no more chills. These chills resulted not from the absorption from the lymphatics, but when the toxins were emptied into the venous system. In cases of appendiceal abscess constitutional symptoms were present until it was walled off; this walling off made a mechanical block and the toxins were not escaping; but so soon as the abscess was opened there occurred lymphatic absorption and a return of the constitutional symptoms. They were in the habit of thinking of cancer being spread in three ways—by the veins, by contiguity of tissue, and by metastasis through the lymphatics. The distribution of the lymphatics was of surgical importance. They were abundant beneath the skin, the mucous membranes, in the groin, axilla, liver, kidneys, base of lungs, etc. They were practically absent from the mucous membrane at the base of the bladder. They were most abundant where the requirements for absorption or tissue metabolism was greatest and *vice versa*. They were arranged in distinct systems. Carcinoma of the bladder grew slowly; on the other hand, carcinoma of the stomach, rich in its lymphatic supply, rapidly involved the lymphatic glands. In the large intestine, except the rectum, carcinoma remained longer than when cancer involved the small intestine. The brain had no lymphatics, except the membrane lining the ventricles. Sometimes they had anastomotic relations, and sometimes they were absolutely isolated from each other. Lymphatics were abundant in the vagina and cervix, but not so abundant in the body of the uterus. Infection of the cervix might cause deep-seated abscesses, while that of the body of the uterus might not. Cancer of the cervix might soon cause death of the patient by extension of the disease through the lymphatics and at autopsy the growth would be found to be widely infiltrating. Cancer of the body of the uterus might be far advanced and yet the cervix not involved. The isolation of the lymphatics in the stomach was most striking; here there were three distinct systems of lymphatics, at the greater, the lesser curvature, and at the fundus. A growth at the pylorus would practically be isolated from the fundus. If cancer involved the pylorus there might be infiltration towards the greater or lesser curvature, but the fundus of the stomach and the duodenum adjacent would remain free. Enlargement of the lymphatic glands was usually over the area drained by those glands. It was given as a very striking fact that normal lymphatic glands could be found only in the child. Dr. Hawks then gave their life history. Lymphatics were abundant in early life, but in old age they, to a certain extent, disappeared. Their influence upon pathological processes was great, as was well illustrated in the fact that general peritonitis from criminal abortion was usual in young girls, but was seldom met with in women of middle life. Age was a great factor, too, in malignant disease; the more abundant the lymphatics, as in the younger patients, the more virulent the disease. Age was a great factor in cancer of the uterus. Cancer of the cervix occurred most often between the ages of forty and forty-five; adenocarcinoma between the ages of fifty and fifty-five. The latter was almost always curable by operation. Cancer of the cervix in the young woman was rapidly fatal. In the old it progressed more slowly. Cancer of the breast occurred comparatively early, say at forty years of age, and metastases occurred. After fifty not only did many of the lymphatics diminish, but the channels in the breast and mediastinal glands became obliterated and operations then gave a better prognosis. After the age of seventy years malignant disease was successfully treated by caustic applications, the cancer in such cases being entirely a local disease.

Dr. Young called attention to the fact that fifteen or twenty years ago nothing was known practically about the lymphatics except those connected with the small intestines, the lacteals, which carried the chyle to the receptaculum chyli, then through the thoracic duct to the left subclavian vein. The lymphatic system was designed to be the protective agency of the body.

Dr. N. L. Wilson of Elizabeth emphasized the point that glandular enlargement meant bacterial invasion, and this was especially true in regard to the cervical glands, whether superficial or deep. One frequently saw enlarged cervical glands becoming infected through diseased tonsils. He said he had seen many cases of this nature, and the enlarged glands receded after the tonsils had been properly treated.

Dr. Emery Marvel of Atlantic City called attention to the work done at the Cornell physiological laboratory, showing that bacteria in the peritoneal cavity could reach the liver through the thoracic duct and in at least fifteen minutes. In tracing the channel the rapidity with which charcoal particles could pass through the omentum and lymphatic channels of the peritoneum and into the liver and spleen was demonstrated. He said he was interested in the phagocytic and enzymodic relationship.

Dr. Hawks closed the discussion.

Otitic Pyemia without Mastoid Involvement.—Dr. W. P. Eagleton presented this paper, which was read by title.

Oration in Surgery.—Dr. Albert Vander Veer of Albany, N. Y., delivered this oration, choosing as his subject "Some Observations on Four Decades of American Surgery." From 1866 to 1906 comprised the time since his entrance into private practise.

First Decade.—Amputations at the thigh then had a mortality of 60 per cent., while to-day it hardly reached 6 per cent. The attempts to save lives in cases of bullet and stab wounds were almost futile, and when the intestinal tract was involved the mortality was little lower than 100; the same mortality attended bullet wounds of the brain and chest. Hospital gangrene, erysipelas, and infectious diseases prevailed. Suppuration was an enemy to successful surgery. The introduction of the drainage tube resulted in much benefit. The war gave the young and middle aged men much to do and post graduate courses in 1865 found these men in a receptive condition to reach out and grasp the marked advances made in the practice and art of surgery. Many became thus early specialists. During this decade were made the discoveries of Pasteur and others in regard to microorganisms. This was one of the most important periods and the evolution of modern surgery seemed to be most marvelous. Few then realized the strides that were being made. For instance, hernia was an operation which was approached with much anxiety and its successful result was greatly to the credit of the operator. Few of those present could realize the amount of discussion that occurred in regard to the disposal of the contents of the sac. A resection of a gangrenous portion of the gut was almost unheard of. With the introduction of the carbolic spray and other antiseptics resections of diseased and injured intestines gradually was introduced. Various methods for treating hernias were employed, but it was only in this last decade that they reached a point where they could deliberately attack a hernia by one method or another. At the end of the first decade the study of microorganisms began, but it was in the second decade that the cultivation of the various germs was made. Erysipelas was beginning to be understood. In the second and third decade the work of surgeons was greatly aided by the establishment of laboratories. The preparation of dressings was worked out, as well as the preparation of patient and surgeon. In the first decade much progress was made in the surgery of the urethra, and the distensibility of certain portions of the urethra was determined. The introduction of the bulbous and olive pointed bougie, the guide and tunnel instruments enabled them to make much progress. In this decade they witnessed the beginning of the operation of oophorectomy. Cholecystectomy was also ushered in. They were also successful in the treatment of tumors of organs and malignant growths of the neck. The treatment of aneurysm by ligature was most impressive. In 1880, under antiseptic precautions, the left iliac was tied for aneurysm of the external iliac. During this period occurred the introduction of the elastic bandage, also the bloodless operations or amputations were carried on with success. There was then much discussion regarding the danger of ligating the large veins. Great advances were made in the treatment of dislocations, and better knowledge was had in the reduction of dislocations of the hip and shoulder by simple manipulation. At this time much attention was given to neuralgias of the feet due to flattened arch, but it was only in this last decade that they found the true cause. Different forms of neuralgia, especially of the fifth pair, were studied, but it was only in this last decade that removal of the Gasserian ganglion was attempted. During this decade was noted a spirit of inquiry on the part of American surgeons and surgery advanced; much was brought about by efforts in antiseptic work. In this decade the operation for an adherent and constricted prepuce was done to relieve partial paralysis of the lower extremity. The operation for vesicovaginal fistula and lacerations of the cervix and perineum shed luster upon this time. Also the removal of carcinomatous tonsils and other operations upon the mouth and neck. The silver wire and other sutures and ligatures were introduced. In this first decade the treatment of fibroid tumors of the uterus was seldom attempted, but in the third decade was introduced a method which gained the confidence of the operating surgeon. And in the fourth decade splendid advances in the operation were made and the operation was done with a very low mortality and the patients were readily relieved. In the first decade great strides were made in the treatment of fractures by plaster-of-Paris and other dressings. The treatment of compound fractures was more successful through antiseptic surgery. In this period was fully developed the control of hemorrhage by torsion. Subcutaneous osteotomy received a marked impetus. Also nephrectomy by the lumbar incision. In the first and second decade tracheotomy was done under trying circumstances, and later intubation. During the fourth decade both disappeared because of the introduction of antitoxin.

Second Decade.—This decade witnessed the introduction of litholopaxy for the relief of vesical calculi, and to-day it was a method of treatment in selected cases. To-day they were meeting with less and less numbers of cases of vesical calculi and they did not meet so many cases as they did thirty years ago. In the second and fourth decade the treatment of stone by suprapubic cystotomy, if large, and by litholopaxy if small, was done. Rectal feeding received attention, which to-day was one of the greatest aids in surgical work. There was also the removal of ovaries and small tumors through the vagina. This decade also witnessed the introduction of carbolic acid and ergot in the treatment of hemorrhoids, but the length of time required and the number of injections which were attended with some risk and mortality caused this operation to be almost entirely abandoned. This was the period that witnessed successful laparotomy for gunshot wounds. At the end of the second and beginning of the third decade local anesthesia with cocaine was studied and introduced and surgery was greatly aided by the use of this drug. Cocaine in the urethra and cavities of the body should be used with great care. Laparotomy under local anesthesia was proper and indicated in cases where patients had passed through a long illness.

Third Decade.—Much was done in this decade. Cystoscopy was made possible. This was a period of wonderful advances in abdominal surgery; likewise in surgery of the spine and in the treatment of fractures and tumors of the spine and cord. Also great advances were made in the treatment of tumors at the base and removal of blood clots in the brain. This subject had received much

attention and to-day the surgery of the brain was quite a problem. The operating part can be done with success, but the ultimate results are not good. Operation for tumors of the brain was most impressive at first. The treatment of spina bifida and meningocele was encouraging. Lumbar puncture for diagnostic purposes was a great aid, and more was to be developed along this line in cases of acute hydrocephalus. Bone lesions were treated with success and great strides were made in the treatment of fractures of the patella. Free incisions could now be made into the joint, and when compared with the results of this during the Civil War made one most grateful. The treatment of fractures had not been sufficiently emphasized, especially the ambulatory treatment which did away with such long confinements in bed in the hospital wards as in the past. In this third decade much excellent work was done in fractures of the neck of the femur. Advances were made in the treatment of uterine fibroids and in the surgery on enlarged prostates, in appendicitis, in work on the kidney, urethra, and gall-bladder. During the third, but more especially in the fourth, was the evolution in the symptoms and treatment of appendicitis. Suprapubic drainage was used in operations on enlarged prostates. At the present time such great advances had been made that prostatectomy by the perineal or suprapubic route had become so firmly established that patients now would readily submit to operation. The third and fourth decades witnessed brilliant operations upon the intestines, much of the work having been first done experimentally in the laboratories. This was the experimental period in work on the abdominal tract. During the second and fourth decades great advances were made in the treatment of perforations in typhoid fever, but had not met with such decided success as they could wish. Nevertheless it was a recognized procedure. In the third decade was discovered the bacillus of tuberculosis. The use of iodoform in surgery of the bones and tuberculosis was attempted. The operation for the removal of tubercular foci about the bones and glands was one of the pronounced advances made by American surgeons. During this decade scientific methods in blood examinations were employed, and were brought to great perfection. The operation for stretching the sciatic nerve was done, but to-day the bloodless operation was done.

Fourth Decade.—More attention was given to anesthetics during this period. Great strides were made in pelvic surgery. It seemed almost impossible to improve upon the work done in the third decade, but great work was done in the treatment of malpositions of the uterus in cases of appendicitis, etc. This fourth decade witnessed marvelous advances made in the operation for the relief of carcinoma of the stomach and intestinal tract. The complete removal of the stomach was one of the most brilliant operations surgeons were called upon to perform. This operation was growing less frequent because of the advances made as the result of studies in diseases of this organ. He referred particularly to the operative work done in gastric and duodenal ulcers. Great advances had been made in the latter part of the fourth decade in surgery of the sigmoid flexure and the rectum. Diagnoses were made now with greater degree of certainty. It was much safer now to open the peritoneal cavity by incision than to trust that the lesion would not produce any perforation of the intestinal tract, or to allow a subperitoneal or an intraperitoneal hemorrhage to be treated by nature than by the assistance of the surgeon. The study of the pathology and treatment of appendicitis made one of the most impressive chapters in American surgery. The third and fourth decade brought forth the successful treatment of lesions in and about the appendix. The necessity for cesarean section and craniotomy grew less and less. The diagnosis and treatment of extrauterine pregnancy were improved upon, and it was difficult to state how many lives were saved by the modern understanding of this condition. During the fourth decade greater advances were made in the treatment of pleuritic effusions than at any time in the history of surgery, as well as operations upon the upper air passages, ribs, and lungs. One pathological condition which was called to the attention of the surgeon was the influence the tonsils exercised in introducing septic microorganisms into the system. The transfusion of blood, milk, and other solutions received careful study and with much resulting satisfaction. Also great satisfaction resulted from the employment of normal salt solutions, as well as direct transfusion of blood, according to Crile. The introduction and employment of the *x*-ray was of value not only in the diagnosis of fractures and dislocations, but in the treatment of lupus and certain forms of skin cancer. The pathology of phlegmasia alba dolens was not yet understood. Dr. Vander Veer told of the many operations that had been tried and found wanting. It was found that the gonococcus was more fatal in its effects than the *Spirochæta pallida*. From the middle of the third decade up to the present time more papers on surgical lesions had been written than at any previous time. He also referred to medical instruction. The surgery of the world was best represented to-day by two famous American surgeons, whose names it was not necessary to mention.

Oration in Medicine.—Dr. Morris Manges of New York delivered this oration, choosing as its title "The Physician and the Medical Press." He said the present was a time of general investigation which even the medical profession had not escaped. The great value of such investigations was that even though they went to extremes a just equilibrium was finally established, and as a result not only were the greater evils corrected, but the minor abuses as well, many of which had long been patiently tolerated and had persisted in spite of spasmodic attempts at correction. The medical profession had been greatly benefited by the pure food and drug investigations, in which both the medical and lay press, but especially the latter, had been so actively engaged. The lay press had been much more active in this matter than the medical press, the latter not having acted as a unit. The careless and venal exploitation of proprietary preparations by physicians had caused editors to regard all contributions on drug studies with suspicion and to refuse them space. As a consequence of this readers of medical journals had been deprived of much useful information concerning the newer drugs. The remedies proposed to correct this evil were better preliminary training of medical students in therapeutics, and the recommendation that the list of drugs prepared by the Council on Pharmacy and Chemistry of the American Medical Association be used as a standard for the publication of occasional papers on drugs; or, the regular publication of reviews, in which the newer preparations were briefly presented. Special stress was laid upon the prohibition of the reprinting by manufacturers for commercial purposes of any article appearing in a medical jounal. A plea was made for honesty on the part of physicians who wrote papers of this kind. The result of the restriction of advertisements would be fewer medical journals. The weaker ones should either lessen the frequency of their appearance, raise their subscription price, consolidate with some stronger journal, or cease to exist. Physicians should do their share in improving the journals by not insisting that every paper which they write should be published. The numerous papers which form part of symposia and were mere reviews should not be printed. Physicians should cultivate brevity in their writings and should study the classics for style and conciseness, a plea being made for a closer study of the classics than was now possible on account of the enormous volume of current medical literature. Finally, it was urged that the press was a mirror of the times, and that if they were to have a

better medical press the doctors must first better themselves.

When and When Not to Operate in Ruptured Ectopic Pregnancy.—Dr. J. S. Baer of Camden read this paper. He said the best time to operate was before rupture had taken place, but unfortunately the condition was but seldom recognized before this occurred. Therefore, when should operation be done after rupture had taken place? He believed it was the time as soon as a diagnosis had been made in nearly, but not all, the cases. He illustrated his opinion by citing a few cases that had occurred in his practice.

Dr. B. F. Baer of Philadelphia endorsed what the reader of the paper had stated, that was, to operate before rupture took place. The time to operate was even before a positive diagnosis was made. Nature's distress sign was written in blood.

Dr. Edward Ill of Newark said that when these patients had severe hemorrhages was not the time to transfer them to the hospital. They should be at once operated upon. By the time they were taken to the hospital they might have lost such an amount of blood as to cause death. Cases that did not need operation were those that for one week, or ten days, or even two weeks, had very little pain; here at the outer end of the tube one would find a mass the size of a hen's egg; if the patient was quiet for a few days that case would not require operation.

Dr. Philander A. Harris of Paterson said he had only one fault to find with the remarks made, and they might possibly mislead unintentionally some general practitioner. If the general practitioner was to perform such an operation he must be competent to judge whether operation was indicated or not. Anyone who had had 130 cases of tubal abortion to care for must have gone through a variety of experiences, and personally he felt that delay would bring them to the tragic stage of the disease, which would be disastrous. He could not honestly lend himself to delay in these cases. In 140 cases he had analyzed he found that ninety per cent. had already consulted a physician in the non-tragic stage of the disease. Only three out of that number, 130, had consulted him as the first physician. Consequently upon the shoulders of the general practitioner must rest a greater responsibility in this matter. Generally patients were not very sick in the non-tragic stage. There were two things which enabled one to make a diagnosis of ectopic gestation, atypical menstruation, and pains. They were atypical because they were out of type in certain particulars. More than twenty per cent. of the cases were curetted for metrorrhagia. When the diagnosis was made, operate.

Dr. G. K. Dickinson of Jersey City said that operation should be done so soon as the diagnosis was made. The two things that led to death in these cases were, first, delay, and, second, the anesthetic.

Dr. Emory Marvel of Atlantic City said that there was probably no one disease so fatal in its results as an untreated extrauterine pregnancy. If the diagnosis was made before rupture the mortality was next to nil. The paper read, however, dealt with cases after rupture had taken place. After rupture had occurred they had then to deal with the blood and blood-vessels, and what surgical principle could be applied except to catch the bleeding points and stop the bleeding. He agreed that the time to operate was immediately after the diagnosis was made. He preferred the abdominal rather than the vaginal route in operating.

Dr. J. M. Rector of Jersey City said that in the tragic cases they were aided by a study of the blood pressure to determine how much shock the patients were suffering from; it showed the condition of the vasomotor apparatus and the cardiac condition. Such a study would enable them to lessen their mortality rate. The indiscriminate use of stimulants was to be deplored.

Dr. J. W. Martindale of Camden referred to two cases of ectopic gestation. One was seen in collapse and fainting. Fainting was nature's way of controlling hemorrhage; if such a patient were stimulated, it would start the bleeding again. It seemed to him that stimulation under these circumstances was prohibitive, and more harm was done than good. In the tragic stage it was best to operate.

Dr. J. S. Baer closed the discussion.

Diet in Pulmonary Tuberculosis.—Dr. Theodore Senseman of Atlantic City read this paper. He concluded that (1) it was not the amount of food ingested that counted, but the amount assimilated. (2) One should improve digestion and allow appetite to follow of its own accord. (3) There was a pivotal point in each patient's digestive ability which should be ascertained. (4) This pivotal point was capable of being raised. (5) All tuberculous individuals showed evidences of digestive derangement; it was folly to attempt to make them do more work when in this condition than when in a healthy state; therefore, stuffing patients with solid food was a mistake. (6) Diet which gave the greatest amount of nourishment and made least demand upon digestive organs was the diet of choice. Raw eggs and milk met these requirements. (7) Each patient had a normal weight beyond which one should not endeavor to force him. (8) This normal weight attained, the smallest quantity of food which would enable him to maintain it was sufficient. (9) So long as this normal weight could be maintained, the patient had nothing to fear from tuberculosis.

Dr. D. E. English of Millburn discussed this paper.

(*To be continued.*)

ILLINOIS STATE MEDICAL SOCIETY.

Fifty-seventh Annual Session, Held at Rockford, May 21, 22, and 23, 1907.

(Special Report to the Medical Record.)

The President, Dr. J. F. Percy of Galesburg, in the Chair.

The scientific work was divided into two sections, medicine and surgery, but all of the papers were read before the general body. One day was set aside for the reading and discussion of papers on medicine, one for papers and discussions on surgery, while the third day was devoted to the discussion of borderline cases.

Symposium on Tuberculosis.—Dr. Robert H. Babcock, Chicago, discussed the early diagnosis of pulmonary tuberculosis. He submitted two propositions: "(1) Pulmonary tuberculosis is curable. (2) Its curability stands in direct relation to the stage of the disease." He pointed out the difficulties in the way of an early recognition of the affection, and mentioned some of the mistakes that are likely to arise. He considered the methods of diagnosis and the data on which the physical diagnosis must rest. As aids to diagnosis, he mentioned tuberculin and the *x*-ray. Tuberculin, when properly used, was safe, and in the majority of cases its reaction denoted tuberculosis. The *x*-ray was not of as much value to the average general practitioner as to the expert; nevertheless, in the hands of the skilled, the fluoroscope or skiagraph would detect lesions which had not developed to such an extent as to cause the manifestation of physical singns in the dungs.

Social Aspects of Tuberculosis.—Dr. Henry B. Favill of Chicago said the technique of the treatment of tuberculosis, both prophylactic and curative, was reasonably well established. Thus far, however, the procedure was complex in its most perfect form, and in this form it was inaccessihle to the enormous majority of those who were, and those likely to become, tuberculous. The move of first importance was to simplify the necessary régimé. This involved the determination of doubtful questions as to climate and the present unnecessary expensiveness of

food. For those not yet ill it involved a practicable plan of hygienic life. The foregoing being determined, the question still remained how to bring into relationship effective means and the individuals needing them. The whole question became, consequently, in a minor degree a medical and hygienic one, and in a chief degree a sociological problem. He offered some suggestions as to the methods to be pursued.

Tuberculosis of the Ocular Structures.—Dr. Casey A. Wood of Chicago divided ocular tuberculosis into extraocular and intraocular. Tubercle of the conjunctiva was probably much more common than was generally believed. Although primary tubercle of the sclerotic was practically unknown, it was often, like the cornea, invaded by uveal tuberculosis. The most important contribution to intraocular tuberculosis in recent years was the monograph by Treacher Collins, based on histological examinations of eighteen eyeballs preserved in the laboratory of the Royal London Ophthalmic Hospital. Tubercle of the iris generally appeared in the miliary form as discrete, disseminated, yellowish nodules, two to three millimeters in diameter. They were associated with keratitis punctata, some pain, and a mild degree of ciliary injection. He described a form of iritic tubercle in which the iritis was the principal clinical factor, and resembled the same disease produced by syphilis. Tuberculosis of the choroid occurred, first, as discrete, miliary nodules scattered over the fundus, and were seen with the ophthalmoscope as gray patches; or, second, as a mass of caseating tissue, formed beneath the detached retina. Tuberculosis of the ciliary body began most frequently in the ciliary processes on the inner surface of the ciliary muscle, where its ciliary plexus was finest. Tubercle of the retina was much rarer than choroidal tuberculosis. Tuberculosis of the optic nerve, originating in its pial sheath as discrete nodules, might become confluent and surround the nerve with a diseased ring.

Dr. Frank P. Norbury, Jacksonville, discussed the nervous and mental phases of tuberculosis, as gleaned from current literature, as well as from his own experience in the detailed study of the neurological and psychological phases of the malady.

Diagnosis and Treatment of Laryngeal Tuberculosis.—Dr. William E. Casselberry of Chicago said that while the diagnosis of tuberculosis of the larynx ordinarily was not difficult, in exceptional cases its substantiation or exclusion was beset with uncertainty. As a basis of comparison, the usual diagnostic data were formulated; the hyperplasia of the interarytenoid fold and vocal processes, of the arytenoids and ventricular bands, sooner or later of the vocal cords, and, lastly, of the epiglottis; the "mouse-nibbled" ulcers which early supervened amid the tumefaction being not conspicuously interblended with cicatrices. The first type, which was described and represented by a case in detail, introduced as fairly typical of a considerable group of cases, was not at all of an unusual sort, being intended to exemplify the familiar preconception of the course of tuberculosis of the larynx, that is, of speedy development, persistent progress, and a rapidly fatal termination. It was named the galloping type, in order further to emphasize the contrasts between it and the one next described, which was named from its salient characteristics, the chronic hyperplastic type. The next case detailed, as fairly typical of this group, presented perplexing uncertainties in regard to the diagnosis, but in the end was well substantiated. Other cases of this type were briefly mentioned in support of the opinion that it was not so very unusual as the scarcity of special mention of it in literature would indicate. Among the other unusual types which were apt to involve uncertainty in diagnosis were those in which the larynx was affected only on one side—the unilateral type, the verrucous type, the so-called conjoined syphilitic and tuberculous type, and the condition of arrest of the disease. Well-authenticated, convincing instances of the latter fortunate termination were discouragingly rare in literature, yet they certainly occurred. He considered the treatment principally in connection with the methods employed in the particular cases detailed rather than in a general way, except to confirm the growing conviction that the treatment of the laryngeal complication was bound up in that of the pulmonary and general state, which, however, did not imply that local measures were without avail, for they certainly were helpful, but only that the general condition should not be subordinated to the local measures.

Management of Tuberculosis.—Dr. Clarence L. Wheaton of Chicago said this subject was of interest to the profession from a medical and humanitarian aspect, and to the public and laity from a social and economic point of view. Much good had been derived from the old teachings, and that which was irrational had been eliminated from the new. He thought there was less experimentation in the attempt to exploit so-called cures. He pointed out the importance of early recognition of tuberculosis, and what clinically constituted early involvement. Twenty and one-third months was the average period of delay following recognition of symptoms referable to the disease up to the time of the patient's arrival in Colorado. He referred to the value of the sanitarium in the management of tuberculosis at home. He submitted a form of ordinance which may be used as a basis for legislation of municipalities regarding tuberculosis, which was practically the same as that drafted by the committee appointed by the Section on Hygiene and Sanitary Science of the American Medical Association. Lastly, he emphasized the importance of reducing the opportunities for infection, promoting the individual powers of resistance, and utilizing all educational influences at our disposal in the management of tuberculosis.

Sanatorium Treatment of Tuberculosis.—Dr. E. H. Butterfield of Ottawa said it was important to consider the construction and location of sanatoria, as essential in the successful treatment. He spoke of the necessity for early diagnosis and prompt treatment both from a humanitarian and economic standpoint. The principles of treatment were not easy of application, and it was necessary to individualize. The public was dangerously educated as to the curability of consumption and the popular misconception as to time limit. The word cure should be used with caution. Climate was not an essential in the treatment.

Dr. J. W. Pettit of Ottawa said it should be repeatedly emphasized that tuberculosis was curable only in the incipient stages, although in exceptional instances some very remarkable results were obtained in far-advanced cases, but the ultimate results in the treatment of the far-advanced cases were not very promising.

These papers were further discussed by Drs. Gray, Brown, Gamble, Marcy, Moyer, Quine, Preble, and Ochsner.

Ulcerative Endocarditis.—Dr James B. Herrick of Chicago said that a complicating nephritis might cause one to overlook primary infectious endocarditis. If one lived up to the rule of trying to find a cause in every case of acute nephritis, and of careful examination of the heart, he would seldom be in doubt as to the existence of endocarditis and an acute infection. We must hope that the antitoxin serums or vaccines for the causal organisms of this serious disease would soon be discovered. If they were discovered, the duty of early recognition of ulcerative endocarditis, together with the microorganisms producing it, would be still more urgent than it was to-day.

Hyperthyroidism.—Dr. Arthur R. Elliott of Chicago considered the forms of thyroid toxemia that were less intense and clinically less distinct than Graves' disease, and due to transient disturbance of the thyroid functions. He cited illustrative cases, after which he discussed the etiology, frequency, and clinical value of the condition.

Nephrolithiasis Urica.—Dr. Alfred C. Croftan of

Chicago discussed some of the newer points in the treatment of this condition. He emphasized the importance of proper diet, the use of alkalies, notably calcium carbonate, and the use of urinary antiseptics. He pointed out how essential it was to remove uratic concretions after they had once formed. He spoke of the remedies that could be employed, and enumerated the fallacies of so-called uric acid solvents. He likewise spoke of the indications for and against the surgical removal of uratic concretions.

Treatment of Polyneuritis.—Dr. JULIUS GRINKER of Chicago said the development and course of this disease may be either acute, subacute, or chronic. The symptoms may refer to motor, sensory, or coordinative disorders, singly or in combination. Early diagnosis must be based upon (1) a proper recognition of disturbances of motion, sensation, or coordination; (2) the state of nutrition of muscles and nerves as evidenced by atrophy, flaccidity, and changed response to electric stimulation; (3) the state of the reflexes was seldom exaggerated, most often reduced or absent. Early treatment should aim to remove the cause or causes; to relieve symptoms; to prevent deformities; to maintain the muscles in a high state of nutrition until normal nerve conduction shall have been reestablished.

Hysteria and Neurasthenia.—Dr. L. HARRISON METTLER of Chicago said that these were distinct clinical entities. They were often observed together in the same patient. When so associated each was fairly distinguishable from the other. Hysteria was primarily a psychosis, a disorder of personality; while neurasthenia was primarily a neurosis, a neurotic inadequacy. Hysteria was a psychophysiological functional defect; neurasthenia was a neurohistological anatomical defect. The cardinal characteristic of hysteria was psychic changeability, while that of neurasthenia was an elemental failure or weakness. All the symptoms of either disease, even when observed together in the same patient, should be analyzed in the light of these respective characteristics. Rational treatment was dependent upon a clear recognition of this distinction between the two diseases. For hysteria the treatment should be psychotherapeutic; for neurasthenia, physical reconstruction.

Septic Tank System.—Dr. E. F. BAKER of Jacksonville said that although the practical working of the septic tank had been known for several years, and in practical operation in a large number of cities throughout the United States and in Europe, still its value was not yet fully realized. From his observations he believed it was the coming method of sewage disposal under the conditions found to exist in many of our populous sections of this and other States.

Operation for Cystocele.—Dr. ARCHIBALD ROBERTSON SMALL of Chicago pointed out the inadequacy of the older methods to produce permanent results. He reviewed some of the work done by other operators during the past five years. The main principle of the operation recommended was to split the anterior vaginal wall from near the meatus to the cervix; widely separate the bladder from the vagina; remove the redundant vaginal wall, and join the cut edges of the vagina by interrupted sutures. In cases of prolapsus of the uterus, he spoke of the necessity of suspending the uterus either by the Kelly method or by means of the round ligaments, in order to give permanent results. He reported a typical case and the result two years and a half after the operation.

Malaria as a Surgical Complication.—Dr. THOMAS M. ADERHOLD of Ziegler presented a paper on this subject, in which he said that patients who harbor the parasite of malaria in their blood, but who show no acute symptoms of malaria, can be operated on without delay and later treated for malaria when the symptoms appear. No temperature either before or after operation could be called malarial unless the parasite was found in the blood. If the temperature arose after an operation, and no parasites could be found in the blood, it should be considered as due to sepsis, and the proper procedures taken. In our present stage of diagnostic science, malaria was a positive finding, and therefore a diagnosis by exclusion was no longer permissible. Malaria was a curable disease, and quinine was the specific.

Puerperal Infection.—Dr. ROBERT T. GILLMORE of Chicago cited the history of a normal case of labor, which was complicated with a severe puerperal infection which manifested itself on the eleventh day. He gave a report of the blood count, and described the convalescent period. He discussed the predisposing and exciting causes of puerperal infection. There was no evidence of autoinfection in this case. As to the predisposing causes, there was no traumatism of the vagina or peritoneum. The patient's labor was ideal, eighteen hours in length, and she was not exhausted. The placenta was intact. The details of her sanitary surroundings were all that could be asked for. After mentioning the exciting causes, he concluded by saying that the streptococci coming from the interior of the uterus had not been carried there by the blood from some focus of infection localized in a remote portion of the body. He gave the reasons why he traced the time of invasion of the streptococci in this particular case to the seventh, eighth, or ninth day after delivery; also why it seemed probable that the douches which were given on the initiative of the nurse about this time were the direct cause of the infection.

Rapid Osteoclasis Versus Osteotomy.—Dr. FRANK B. LUCAS of Peoria dealt with operative procedures for the correction of bow-legs, anterior bent tibias, and knock-knees in children. He took an account of the lack of technique given by orthopedic authors on the use of the Grattan osteoclast, and Blanchard was freely quoted as an authority on account of over seven hundred operative cases by the above bloodless method. Cuneiform osteotomy was particularly decried as producing shortening in the tibia, whereas osteoclasis produces lengthening, thereby increasing stature. Manual correction of bow-legs in the early period, followed by repeated casts, was given as the best method of correction in infants just beginning to walk. Braces were slow, tiresome, and were apt to produce loose knee-joints as well as sores from pressure. The fracture, usually a four-fifths or green-stick, as produced by the Grattan osteoclast, could be completed manually, if necessary, and the in-or-out twisted tibial deformity corrected by hand, the cast being applied and the leg held in overcorrection until plaster was firm. About four weeks in plaster was sufficient, when the child might be allowed to walk without the aid of any appliance or brace. In correction of knock-knee there was usually only an osteokampsis or bending of the femur at its lower third, and legs were put up in overcorrection so they resembled bow-legs while in plaster. The technique of the above was given in full. The author cited three cases showing good results, and presented illustrations of the method as advised. The advantages of osteoclasis were set forth, and an appeal made for adoption of the improved method for correction of these "brace-ridden" deformities, and the hope expressed that orthopedic authors may cease to give the profession a wrong impression of the value of osteoclasis.

Paralytic Deformities of the Legs.—Dr. E. W. RYERSON of Chicago discussed two varieties of paralytic deformities of the leg, namely, the cerebral or spastic paralysis, and anterior poliomyelitis. He said medical treatment was of little value. Mechanical treatment was described. Operative treatment was of several kinds, such as tenotomy, nerve grafting, and tendon transplantation. These procedures were described in detail.

President's Address.—Dr. J. F. PERCY of Galesburg, in his presidential address, said, among other things, that the medicine of the future would find the physician recognizing his need for dependence upon his colleagues. Medicine of the future would understand and correct the loss

that was sustained in our day by failure to recognize that back of every physician were ambition, hope, aspirations, good fellowship, and the sincere desire to be well thought of by his fellows. The days of radicalism in medicine were gone, never to return. The day of schools in medicine was also gone, never to return. The statement of a brilliant writer recently made that "Medicine is an art that sometimes cures, often relieves, and always comforts," would, in the light of the forward movements of the pointer on the dial of Time, be revised so as to read, "Medicine is the science that always comforts, always relieves, and always cures." At present the laboratories and hospitals were furnishing valuable knowledge for the prevention and cure of disease faster than it could be given to or made practical use of by the physician in his everyday work. This was one of the problems for future medicine. Medicine of the future would require that the physician begin his work with a more than adequate preliminary literary and scientific education. "Clothed with character, robed in the mantle of ceaseless toil for the sick, underpaid, often unappreciated, frequently legislated against, carrying the rod of science with an altruism that knows no limits, the physician of to-day, of yesterday, and of to-morrow is only among his peers when in the company of the earth's most exalted."

Dr. Robert B. Preble of Chicago delivered the Address in Medicine. He selected for his subject, "The Rôle of Gross Parasites in the Diffusion of Infectious Diseases."

Dr. Charles H. Mayo of Rochester, Minn., delivered the Address in Surgery, in which he discussed the surgical treatment of hyperthyroidism or exophthalmic goiter.

Acute Mastoiditis.—Dr. L. R. Ryan of Galesburg pointed out the frequency of acute otitis media purulenta in our climate affecting all ages and classes. The most dangerous complication was mastoid abscess. He described the methods of prevention, and said that if abscess occurred an operation was almost imperative. The Stacke-Schwartz operation was seldom necessary. Wilde's incision was adequate in that it seemed to meet all the indications, if properly done. This operation should be performed early. He cited a series of cases ranging in age from two years to seventy years, all of which were cured, without complications or recurrence of the disease, by the Wilde incision alone.

Plastic Surgery of the Urethra.—Dr. G. Frank Lydston of Chicago demonstrated his method of reconstructing the penile urethra and closing urethral fistula by flaps from the scrotum and penis, making a double-layered floor. By his new method the new urethral tube was entirely lined with skin epithelium, hence it could not undergo cicatricial contraction and closure. He reported a number of cases operated on successfully by this method. The author claimed that the ordinary methods were failures, or worse.

Scopolamine and Morphine as a Preliminary to General Anesthesia.—Dr. Clifford U. Collins of Peoria said the advantages derived from this method were: *First*, the tranquil drowsy state of mind which it produces in the patient before the general anesthetic is administered. If it does nothing else, this should be sufficient to give it a permanent place in the anesthesias of the future. The patient feels an irresistible tendency to close his eyes and sleep. *Second*, by the preliminary use of scopolamine and morphine the tranquil condition of sleep is produced in any patient, regardless of age, with the same desirable results. *Third*, a great deal less of the general anesthetic is required. Chloroform and ether have distinct dangers, and it is probable that with the administration of a lessened amount, the dangers will be correspondingly lessened. For this reason a patient is safer in the hands of an inexperienced anesthetist with the preliminary injection than without it, although an experienced anesthetist should always be obtained when possible. *Fourth*, scopolamine produces a dryness of the throat which is very desirable when ether is administered, because it prevents the flow of mucus usually produced by the ether and lessens the dangers of aspiration of this mucus into the respiratory tracts. *Fifth*, the patient usually sleeps for three or four hours after the operation. The smarting, burning pain of the incision has usually ceased before the patient awakes. *Sixth*, the postoperative vomiting is markedly lessened. About one patient in twenty will vomit several times afterwards, but the remainder will be spared this painful, distressing complication. The only disadvantage is the varying effect of the single dose on the patients. A few patients will not get the full beneficent effects of the preliminary dose, although all are benefited to some degree.

Varicose Veins and Ulcers of the Leg.—Dr. W. S. Royce of Chicago described briefly the pathology and etiology of these conditions, and mentioned the unsatisfactory results as well as the various forms of treatment. He spoke of the class of patients that were affected as well as the large number. He described the abmulatory treatment which, he said, gave great relief, and sometimes effected a permanent cure, requiring no loss of time on part of the patient. He illustrated his method of treatment on models, and gave a short comparison of it with other treatment.

Gall-Bladder Surgery.—Dr. J. E. Allaben of Rockford described three unusual cases. The first was one of exophthalmic goiter, with large solitary stone in the gall-bladder, with adhesions about the gall-bladder and pylorus causing symptoms which simulated benign pyloric stenosis. A cholecystotomy was done, with death on the third day from pulmonary edema. Case II was one of cholelithiasis in which a cholecystotomy was performed, with death on the third day. Although a post mortem was made, the cause of death was obscure, but it was probably due to autointoxication. Case III was one of cholecystitis which complicated pregnancy, and was mistaken for pernicious vomiting of pregnancy. The gall-bladder symptoms simulated gallstone colic. The woman was delivered of a healthy full-term child. Four months later return of symptoms necessitated a cholecystotomy. She was relieved for one year, when the symptoms returned. Examination revealed a displacement of the right kidney of second degree; the kidney was held in place by a Dunning kidney pad and abdominal supporter. The woman had relief for one year, when her symptoms returned. It was found that adhesions caused a partial obstruction of the pylorus. Operation was done, and the numerous adhesions about the pylorus were released. Cholecystectomy, with E. W. Andrews' operation, colohepatopexy (colon substitution), was performed. Death occurred on the third day from hemorrhage of the liver.

Otitic Brain Abscesses.—Dr. Frederick K. Sidley of Peoria reported three cases, and said that surgical interference in brain complications due to ear disease was unsatisfactory in a large percentage of cases. This was chiefly due to the fact that the symptoms and serious condition was not recognized until the focal symptoms had become established and the meninges were involved. Brain abscesses had an unknown beginning and many developed from diseases of the tympanic cavity that were regarded as simple and not serious. All discharging ears should be considered serious and the first step in the treatment of any brain complication from ear disease was the prompt diagnosis and treatment of the first discharge.

Practical Venereal Prophylaxis.—Dr. Denslow Lewis of Chicago said that professional opinion now endorsed publicity and advocated instruction of the laity. He described the methods that were favored by State and national societies. He criticised the attitude of the lay press, and pointed out the difficulties to be overcome in reaching the public. He pointed out the objections to obscenity

laws which he said were shown to be unjust and uncertain. He considered the prostitute as a purveyor of infection, and said there should be recommendations for more consistent appreciation of her position in society. He advocated judicious care and quarantine as a factor in venereal prophylaxis.

Indications for Cesarean Section.—Dr. E. C. Franing of Galesburg read a paper in which he presented the following conclusions: (1) Practise pelvimetry on all primiparæ. (2) Do pelvimetry on all multiparæ who have given a history of difficult labors. (3) In all cases of flat rachitic pelvis, with true conjugate of 8.5 cm., or less, prepare for and do cesarean section. (4) All cases with true conjugate between 8 and 8.5 cm. must be looked upon as probable cesarean sections. Allow patient to go to term and into labor. Prepare patient thoroughly as for surgical operations, and make vaginal examination for correct position, etc. Make no more examinations until patient has been in actual labor four hours, when, unless the head has made a decided attempt to enter the pelvis, do a cesarean section. If the head enters the pelvis, but is later arrested, choose between forceps, symphyseotomy and cesarean section. (5) All cases with a true conjugate between 8.5 cm. and 9.5 cm. should be considered as possible cesarean sections, and the same procedure may be instituted as in conclusion four. (6) The fetal mortality is so high in prematurely induced labors that it is totally unwarranted as compared with cesarean section, unless the latter is especially contraindicated. (7) In face of the fact that the maternal mortality in cesarean section is not greater than by any other method of treatment, and that of the child mortality is much reduced by the former, the interest of the child will force us to honor cesarean section more often in the treatment of placenta prævia than at present. (8) In all cases of placenta prævia centralis or with rigid os, unless special indications to the contrary should be absolute, indications for cesarean section in favor of the child. (9) In all cases of placenta prævia have the patient under the best conditions and ready for any operation. Begin the treatment by the expectant method, and the moment the conditions arise which threaten either the mother's or the child's life, which cannot be controlled by any other method, do abdominal section, unless the mother is in a weakened condition, and she can be saved by extracting a live or dead child by forceps or version. (10) Never do abdominal cesarean section on an eclamptic unless she has a considerably contracted or obstructed pelvis, or to save a live child from a dying woman. (11) The classic Saenger operation should be done in all cases, except in tuberculosis, malignancy, tumors, or sepsis, in which hysterectomy is the operation of choice.

Opsonins, Opsonic Index, and Vaccine Therapy.—Dr. John C. Hollister of Chicago said that to aid a patient in his struggle against infection we should strengthen his phagocytic power. If this phagocytic power depended on white blood cells and opsonins, we must have a method of determining what was the condition of such factors, and, if they were insufficient, we must be able to cause an increase in their number. We could increase the number of leucocytes, but we knew that this was not the same as increasing phagocytosis. Wright had not only perfected a method of determining the strength of the opsonic power, but also of increasing it if it was low; the first by what was known as the opsonic index, the latter by vaccine therapy, and by Wright's methods we could not only estimate the patient's phagocytic resisting power to individual infections, but we could help him to get well by raising that power. We must aid phagocytosis in order to strengthen resistance. Phagocytosis had two factors, leucocytes and opsonins. We could increase the number of leucocytes, but that was of limited value. We could estimate the opsonic strength of the infected patient, and we could be of marked assistance if we were able to raise and maintain his opsonic index. The presence of invading bacteria stimulated further elaboration of opsonins in the serum. This was not only so if live pathogenic germs gained access, but it had been found to be true if one took the same germs and sterilized them by heating, thus destroying their pathogenic power, and then injecting them into the tissues of the body. This was what was meant by vaccine therapy. We injected into a patient whose opsonic, and therefore phagocytic, power was low a sterilized culture of the very germ that was causing his individual disease, and when this was done by a definite careful method, it was found that his opsonic index could be raised, and that when so raised his tendency was toward recovery. In what infections could we say vaccine therapy was of definite value? *First*, in staphylococcus infections; acne, furunculosis, carbuncles, and the more generalized forms of staphylococcus invasion. *Second*, in infections by the colon bacillus; pyelitis, cystitis, pleuritis. *Third*, in infections by the tubercle bacillus, especially in localized tuberculosis of the skin, bones, joints, and genitourinary tract. The author had not yet had sufficient experience in the treatment of pulmonary tuberculosis to draw conclusions. *Fourth*, as to infections by the gonococcus. Here he could say, judging from about twenty cases, that a person infected by that organism acutely or chronically usually had a low index, and that this low index could invariably be raised and maintained at a higher level. After a sufficient number of cases had been treated by the gonococcus vaccine without other measures, he thought we would be able to estimate the actual results. The outlook was promising in spite of the fact that the technique was difficult.

The Treatment of Pelvic Infections.— Dr. Channing W. Barrett of Chicago discussed this subject with special reference to the technique of pus tube operations. His conclusions were: (1) Pelvic infection is a destructive process, sometimes causing only mild disturbances, sometimes causing death with or without provoking a marked inflammatory reaction. (2) Pelvic inflammation is a protective process which may or may not save the life of the patient, according to the virulence of the infection, and the completeness of the inflammatory reaction. (3) A pelvic inflammation has no power of self-extension, but tends rather toward repair. (4) Puerperal infections are usually due to the introduction of bacteria during or after delivery, but may be caused by the presence of germs in the vagina, cervix, pus tube, or ovary, appendix, bowel, or peritoneum during delivery or the puerperium. (5) With the onset of puerperal infection all stitches should usually be removed and vagina and uterus determined free from foreign material with as little damage to the linings of these organs as possible. (6) During the acutely active stage of a pelvic infection the patient should usually receive nonoperative treatment until it may be determined that drainage or removal of some organ will remove or decidedly lessen the source of infection. Then drainage, removal of the uterus, tube, or ovary may be indicated. (7) The removal of acutely inflamed pelvic organs is not indicated for this inflammation *per se*. (8) Nonpuerperal, nonoperative acute infection is usually, but not necessarily, of gonorrheal origin. (9) An acute primary infection of the tubes and ovaries should be treated conservatively in the beginning to save these organs. (10) During an acute attack of infection, if the patient is not doing well, drainage may be instituted to hasten convalescence or save the life of the patient. (11) Chronic pus tubes should be removed. (12) Immediately upon the lighting up of an acute infection in old pus tubes a radical operation may be advised, but should this be delayed until infection is distributed through the pelvis, drainage is more desirable if operation becomes necessary. (13) Two safe operations are always preferable to one

dangerous one. (14) A radical operation should aim to do the least possible traumatism to tissues that are to be left and cause the least possible distribution of infected material. (15) To that end he commends the technique he described of severing the tube before a forcible effort is made to lift it out of the cul-de-sac.

The following papers were also read: "When Should Gastric Ulcer Be Treated Surgically and When Medically?" by Dr. Bertram W. Sippy, Chicago; "Achylia Gastrica in Its Relation to Intestinal Function," by Dr. Frank Billings, Chicago; "Progressive Infective Gangrene and Allied Affections," by Dr. L. Ryan, Chicago; "Indications for, Technique of, and Results in Surgery of the Peripheral Nerves," by Dr. John B. Murphy, Chicago; "A New Modification of the Primary Position in the Bloodless Treatment of Congenital Hip-Joint Dislocation," by Dr. Frederick Mueller, Chicago; "Post-Operative Gall-Bladder and Gall Duct Fistulæ," by Dr. M. R. Barker, Chicago; 'Emesis During Period of Gestation," by Dr. Edwin M. Minnick, Moline; "Feigned Eruptions," by Dr. Frank Hugh Montgomery, Chicago; "A Report of Two Unusual Cases," by Dr. David Lockie, Pontia; "Exophthalmic Goiter," by Dr. O. M. Steffenson, Chicago; "Partial Thyroidectomy as the Treatment of Exophthalmic Goiter," by Dr. A. P. Heineck, Chicago; "Interstate Medical Reciprocity, and Our Degraded Certificate," by Dr. C. T. Robinson, Edwardsville.

Officers for the Ensuing Year.—*President,* Dr. William L. Baum, Chicago; *First Vice-President,* Dr. C. W. Lillie, East St. Louis; *Second Vice-President,* Dr. T. H. Culhane, Rockford; *Secretary,* Dr. E. W. Weis, Ottawa, reelected; *Treasurer,* Dr. E. J. Brown, Decatur, reelected. *Delegates to the American Medical Association,* Drs. Frank Billings, Chicago; J. R. Hollowbush, Rock Island, and C. S. Bacon, Chicago; *Alternates,* Dr. G. D. Smith, Elizabeth; Chas. B. Horrell, Galesburg; Dr. Robert T. Gillmore, Chicago; Dr. E. B. Montgomery, Quincy; Dr. C. M. Jack, Decatur; Dr. Wm. L. Ballenger, Chicago, and Dr. S. C. Stremmel, McComb.

Peoria was selected as the place for holding the next annual meeting.

Philadelphia County Medical Society.

At a stated meeting held April 24, Dr. T. H. Evans presented a paper entitled "Status of the Question of Sugar in Cases of Cancer." Dr. James E. Talley read a paper entitled "Report of a Case of Intermittent Claudication." The patient was a man about sixty years old who had been exposed to poisoning by lead, antimony, and mercury, and had indulged excessively in alcohol and tobacco. He presented redness, and at times cyanosis, with a sense of heat and swelling in the lower extremities, when the feet were held in a dependent posture, the members losing their color and becoming almost white when elevated. There was difficulty in walking, locomotion being interfered with during exercise. Trophic ulcers had formed on the feet, and amputation of one of the toes became necessary for gangrene. The circulation through the arteries of the lower extremities was greatly diminished, no pulse being distinguishable in the popliteal and dorsalis pedis arteries. Dr. Walker S. Cornell read a paper entitled "Eyestrain in School-children, Based upon a Routine Study of 1,000 Cases." Observations made in the capacity of Medical Inspector of the Bureau of Health showed that almost one-third of the children in the public schools have defects of refraction, interfering with their comfort and scholarship. The failure to make the necessary corrections lies in part and largely at the door of indifferent or uninformed parents, but is due in small degree also to the negligence of physicians. Dr. E. J. G. Bearsley read a paper entitled "Report of Three Cases of Splenomedullary Leukemia, with Blood-findings." One of the cases was of six years' standing and had exhibited numerous remissions and exacerbations, sometimes in conjunction with, at other times independently of, therapeutic procedures. The exact nature of the affection is not known, although it is supposed to be due to some disorder of the hemopoietic system. Therapeutically, the best results appear to have been brought about by the administration of Fowler's solution of potassium arsenite in ascending doses, and the use of the x-ray, preferably applied over the long bones.

Therapeutic Hints.

Coryza.—Waxham says that if given early the following acts almost as a specific:

℞ Quin. salicyl. . . . . gr. iss
Acid arsenos. . . . . gr. 1-120
Ext. belladon. . . . . gr. 1-20
Capsici. . . . . gr. 1-4

Two capsules of this composition every hour for three hours, and then one every three hours.

—*Denver Medical Times.*

Tape Worm.—

℞ Oleoresinæ aspid. . . . . ʒi
Ol. terebinth rect. . . . . gutt. xx
Chloroformi. . . . . gutt. xv
Mucilag. acaciæ. . . . . q. ad. ʒi

M. S.: One-half at night and the other half the following morning.

Dysmenorrhea.—

℞ Morph. hydrochlor. 0.02
Extr. hyoscyam. 0.1
Butyr. cacao. 2.0

M. ft. suppositor.

—Kantorowicz.

Diarrhea.—

℞ Resorcini. . . . . gr. xii
Glycerini. . . . . ʒiv
Tr. opii. . . . . ℥x
Aq. cinnamomi. . . . . ad. ʒiv

M. S.: One tablespoonful for an adult; one to two teaspoonfuls for a child.

—Burney Yeo.

Atonic Dyspepsia.—

℞ Tr. card. co. . . . . ʒss
Tr. rhei. co. . . . . ʒss
Sodii bicarb. . . . . gr. xv
Inf. columb. . . . . ad. ʒi

S.: Take three times a day.

—Lucas.

Sea Sickness.—

℞ Cerii oxalatis. . . . . gr. ii
Tr. valerian co. . . . . ʒi
Aquæ. . . . . ʒi

S.: Take every one-half hour till relieved.

—Walsh.

Orchitis.—For first six days:

℞ Guaiacol. . . . . ʒiiiss
Adipis. . . . . ʒii

S.: Rub in gently and apply on lint. Envelop testicle in cotton and apply snug suspensory bandage. After the first week:

℞ Ung. hydrarg. . . . . .
Ung. belladon. . . . . .
Ichthyol . . . . . .
Lanolini. . . . . āā ʒii

S.: Apply locally.

—Christian.

Asthma.—A. R. Edwards recommends the following combination in the treatment of bronchial asthma:

℞ Ext. grindeliæ robustæ fl. . . . . fʒj
Tinct. lobeliæ. . . . . āā fʒij.
Tinct. belladonnæ. . . . . āā fʒij.
Potassii iodidi. . . . . ʒiss.
Syrupi. . . . . fʒj.
Aquæ, q. s. ad. . . . . fʒiv.

Misce. S.: One teaspoonful four times a day.

H. C. Brown recommends the following:

℞ Sodii arsenatis. . . . . gr. iss.
Aquæ. . . . . fʒx.

Misce. S.: One tablespoonful before breakfast and supper. Or—

℞ Antimonii et potassii tart. . . . . gr. j.
Potassii chloratis. . . . . gr. v.
Aquæ, q. s. . . . . fʒiv.

Misce. S.: One teaspoonful every two hours.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Minnesota State Board of Medical Examiners.

January, 1907.

ANATOMY AND HISTOLOGY.

1. Describe the membranes covering the brain, in their order, from without, inward, giving the number of and peculiarities of each.
2. Describe the mammary glands and give the blood and nerve supply.
3. Describe the stomach, fully, giving blood and nerve supply and its anatomical relations to surrounding parts.
4. Give the fetal circulation.
5. Describe the shoulder joint and name the muscles covering it and their relation to it.
6. Define Histology.
7. Name the four fundamental elementary tissues.
8. Define Metabolism.
9. Describe lung tissue (a terminal bronchiole and pyramidal mass that it leads to) fully.
10. A hair is composed of how many strata? Name them in their order.

PHYSIOLOGY.

1. Give, somewhat in detail, the physiology of the kidney, with a sufficient anatomical description (preferably with diagram), to make your meaning plain.
2. The same of the liver.
3. Of what does the sympathetic nervous system consist, and where is it located, and how divided as regards location, and what is its function?
4. What centers are located and arranged alongside the fissure of Rolando?
5. Describe human blood, giving reaction, specific gravity, constituents, etc.
6. What are the functions of epithelial tissue?
7. In a lesion involving the third frontal convolution on the left side (in a right handed person), what function would be interfered with?
8. Describe the pulmonary circulation, and the changes which are produced in the blood by aëration.
9. Trace the different steps in the digestion of a bolus of food consisting of proteids, fats, starches, and sugars.
10. What is the composition, reaction and function of the pancreatic juice?

CHEMISTRY, TOXOLOGY, AND URINALYSIS.

1. How would you determine the presence of mercury in a solution? In a solid or powder?
2. How would you determine the presence of silver in a solution? In a solid?
3. Give test of iodine.
4. Give test for the presence of hydrocyanic acid.
5. Give test for the presence of morphia.
6. Give test for the presence of strychnia.
7. How determine if urea or the urates are present in excess?
8. How determine the presence of acetone?
9. How determine the existence of oxaluria?
10. Give symptoms and treatment of acute poisoning by salicylic acid or the salicylates.

MEDICAL JURISPRUDENCE.

1. Define illusion, hallucination, and delusion, and give example of each.
2. What are the post mortem signs found after asphyxia in the new born? After strangulation?
3. How is criminal abortion commonly produced? How detected in the living and dead?
4. What are the effects of prolonged exposure to cold, and the post mortem appearances which follow?
5. Upon what does the poisonous action of coal gas depend?

PREVENTIVE MEDICINE.

1. A case of small-pox is discovered in a lodging house; what steps should be taken to prevent the spread of the disease?
2. What are the dangerous impurities in the air of crowded and unventilated rooms?
3. Describe sand filtration of water on large scale, construction of filter; and explain action in purifying water.
4. Give some simple precautions for the conduct of the tuberculous patient to prevent the spread of the disease.
5. In a system of house plumbing, what is a trap, give construction, location and use.

MATERIA MEDICA AND THERAPEUTICS.

1. Name the official soluble Salts of Iron.
2. Opium:
   (a) Give action on man of *Therapeutic* and of *Toxic* doses.
   (b) Name chief preparations of (not alkaloids), with dose of each.
   (c) Contraindications for use.
3. You wish to prescribe Ammonium Salicylate, but find your druggist out of stock; write an extemporaneous prescription which will give the required drug in solution in proper dosage for a case of acute inflammatory rheumatism.
4. Give the average adult dose of the following:
   (a) Arsenous Acid.
   (b) Fl. Ext. Cannabis Indica.
   (c) Ext. Hyoscyamus.
   (d) Heroin Hydrochlorid.
   (e) Hydrocyanic Acid dilute.
   (f) Tr. Aconite, U. S. P.
   (g) Lead Acetate.
   (h) Guaiacol Carbonate.
   (i) Sulphonal.
   (j) Acetanilid.
5. Criticise the following prescription:

   R Tr. ferri Chloridi dr. ij.
   Acid Acetic dil. dr. iij.
   Liq. Ammon. Acetatis. oz. iij.
   Liq. Potas. Arsenitis dr. ss.
   Glycerin } aa dr. vi.
   Elix. Aromat. }
   Aquæ pur. q. s. ad oz. vi.
   Misce et sig. A tablespoonful in a little water three times a day after eating.

6. What is the action of strychnia upon the sympathetic nervous system?
7. Give directions and write a prescription for the treatment of chronic dry eczema of the hands.
8. Outline treatment for a case of hemoptysis, and give your reasons for the treatment you advocate.
9. Discuss the use of the nitrite group of drugs in *shock*.
10. Give directions and write a prescription for the treatment of scabies.

PATHOLOGY.

1. Describe the morbid anatomy of the various forms of cystitis.
2. What are the three main factors recognized as causing hemopholis?
3. Describe the pathology of myxedema and cretinism.
4. Describe the pathological changes of the vermiform appendix in the different forms of appendicitis.
5. Give the pathology of chronic interstitial hepatitis.

BACTERIOLOGY.

1. What are the five nutrient media generally employed in the culture of pathogenic bacteria?
2. Give a brief history of the method of immunization against three infectious diseases where causative agents are known.
3. What bacteria may we expect to find in a phlegmon? What in a so-called "cold abcess?"
4. What are the microscopic findings in actinomycosis in the human being?
5. Give method of staining tubercle bacillus.

MEDICINE.

1. From what conditions must apoplexy (cerebral hemorrhage) be differentiated?
2. Compare the physical signs of pericardial effusion and of an enlarged heart.
3. What is leukemia?
4. Pneumothorax: definition, cause, symptoms.
5. Give the symptoms and prognosis of peripheral facial paralysis.
6. Give the symptoms and dietetic treatment of infantile scurvy.
7. Define impetigo.
8. Contrast the period of incubation, stage of invasion and character of the eruption in measles and scarlet fever.
9. How does syphilis affect the bones?
10. Name a common form of tape worm and describe its life history.

SURGERY.

1. Normal or physiologic salt solution, its composition, preparation and uses in surgery.
2. Forward luxation of head of radius; symptoms, signs, and treatment.
3. Describe briefly a compound comminuted fracture of the long bones, prognosis and treatment.

4. Acute osteomyelitis, pathology, and differential diagnosis.
5. Prostatic enlargement, pathologic varieties, symptoms and treatment.
6. Differential diagnosis between gastric and duodenal ulcer.
7. Differential diagnosis between nephrophthisis and nephrolithiasis, and how do you determine on which side the lesion exists?
8. Carbuncle, description and treatment.
9. Pterygium; describe in detail. Operation for its successful removal.
10. Traumatic cataract, treatment.

OBSTETRICS.

1. Bound the true pelvis? Define brim? False pelvis?
2. Give etiology, prognosis and general management of puerperal insanity?
3. Name and define five of the most important signs of pregnancy at four months.
4. Give early symptoms of placenta prævia; also, your management of a case including active treatment.
5. Case: primipara in labor at term—pains have continued six hours—os rigid and undilated. Give your method of procedure.

DISEASES OF WOMEN.

1. Name three varieties of vaginitis with causes and symptoms of each?
2. Give causes and treatment of chronic non-specific endometritis?
3. What is the significance of uterine hemorrhage independent of menstruation or pregnancy?
4. What are the indications for tracheolorrhaphy? Describe the operation fully?
5. In what gynecological diseases and conditions do we find painful defecation a prominent symptom? Bearing down feeling? Leucorrheal discharge?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS.
January, 1907.

ANATOMY AND HISTOLOGY.

10. The layers of a hair, in order, from without inwards, are:
Dermal sheath.
Hyaline layer.
External epidermic coat.
Internal epidermic coat. { Henle's layer. Huxley's layer. Cuticular layer.
Cortex.
Medulla.

PHYSIOLOGY.

3. "The sympathetic nervous system consists of (1) a series of ganglia connected together by a great ganglionic cord, the gangliated cord, extending from the base of the skull to the coccyx, one gangliated cord on each side of the middle line of the body, partly in front and partly on each side of the vertebral column; (2) of three great gangliated plexuses or aggregations of nerves and ganglia, situated in front of the spine in the thoracic, abdominal, and pelvic cavities respectively; (3) of smaller or terminal ganglia, situated in relation with the abdominal viscera; and (4) of numerous fibers." (Gray's *Anatomy*.)

Its *functions*: "It may safely be said that the sympathetic system has, to a great extent, a controlling influence over the secretion of most of the glands, the lacrymal, the salivary, the sweat glands, the glands of the stomach and intestines, the liver, the kidney, etc.; that it presides over the circulation by regulating the caliber of the blood-vessels and the action of the heart; that it influences respiration; and, finally, that all involuntary muscles, those of the digestive apparatus, of the genitourinary system, of the hair follicles (pilomotor nerves), are under its control to such extent that, for instance, in certain mammalians the bladder still continues to fulfill its function for weeks after all the cerebrospinal motor nerves leading to it have been severed. In short, we find that all vegetative life of the organism is, to a greater or less extent, under the control of the sympathetic system. Therefore it may properly be called the vegetative nerve system *par excellence*." (*Reference Handbook of the Medical Sciences*.)

4. The *motor* centers are located and arranged alongside the fissure of Rolando. At the upper part of the convolutions on each side of this fissure are areas connected with the movements of the lower extremities; then from above downwards are located the centers for movements of the shoulders, arms, wrists, fingers, face, lips, tongue, and larynx and pharynx.

6. The functions of epithelial tissue are: (1) Protection, (2) secretion, (3) motion (ciliary), (4) special sensation, (5) absorption.

7. The lesion described would produce motor aphasia.

10. *Pancreatic juice. Composition*: Water and solids, the latter consisting of three enzymes (trypsin, amylopsin, and steapsin), proteid material, soaps, fats, lecithin, and inorganic salts (carbonate of sodium, chloride of sodium, and phosphates of sodium, calcium, and magnesium).

The *reaction* is alkaline, due to sodium carbonate.

The *functions*: (1) It changes proteids into proteoses and peptones, and afterwards decomposes them into leucin and tyrosin; (2) it converts starch into maltose; (3) it emulsifies and saponifies fats; and (4) it causes milk to curdle.

CHEMISTRY, TOXICOLOGY, AND URINALYSIS.

1. To determine the presence of *mercury* in a *solution*: Add sulphuretted hydrogen; a black precipitate results, which is insoluble in hot nitric acid.

To determine the presence of *mercury* in a *solid or powder*: Heat in a glass tube with sodium carbonate; a gray sublimate of metallic mercury will be deposited on the cold part of the tube.

2. To determine the presence of *silver* in a *solution*: Add hydrochloric acid; a white, curdy precipitate results, which is soluble in ammonia, insoluble in acids, and becomes dark on exposure to the light.

To determine the presence of *silver* in a *solid*: Fuse on charcoal; a silver globule results.

3. Test for *iodine*: Add starch paste; a deep blue color results.

4. Test for presence of *hydrocyanic acid*: Add ammonium sulphydrate and evaporate to dryness; then add solution of ferric chloride; a red color results.

5. Test for presence of *morphia*: Add solution of neutral ferric chloride; a blue color results.

6. Test for presence of *strychnia*: Add concentrated sulphuric acid; a colorless solution is formed. If a crystal of potassium bichromate be drawn through this solution, it is followed by a track of color which is first (for an instant) blue, then violet, then rose-colored, and finally yellow.

8. To determine the presence of *acetone*: Add a few drops of freshly prepared solution of sodium nitroprusside, and then some potassium hydroxide solution; the fluid is colored ruby red, and on supersaturation with acetic acid becomes purple.

9. To determine the presence of *oxaluria*: Microscopically examine the sediment of the urine; note the presence of dumb-bell shaped crystals, or highly refracting octahedral crystals.

10. *Symptoms* of acute poisoning by salicylic acid or the salicylates: "Profuse sweating, roaring in the ears, dimness of vision, headache, partial or total deafness, and a decided fall in temperature. The pulse becomes weak and relaxed, and finally ptosis, strabismus, and general paralysis ensue. The urine and feces are passed involuntarily, and the urine is olive-green in color. The respirations at first are quickened and deepened, but finally become shallow and feeble, death ensuing from respiratory failure. If the dose is sufficiently large, the blood is involved and the corpuscles rapidly break down." (Hare's *Therapeutics*.)

Treatment: Lavage, purgatives, milk, and white of egg.

MEDICAL JURISPRUDENCE.

1. A *delusion* is a belief in something which has no real existence, but is purely imaginary; and out of which the person cannot be reasoned. An *illusion* is a false or perverted impression, received through one of the senses. An *hallucination* is the same as an illusion, but without any material basis.

If an individual believes himself to be made of glass, and is afraid of being touched lest he be broken, he is suffering from a *delusion*. If the whistling of the wind is mistaken for a voice telling a person to do a certain thing—that would be an *illusion*. If a person fancied he heard a voice when there was nothing at all to be heard, that would be an *hallucination*.

4. *Prolonged exposure to cold* causes first a lividity and then a whiteness of the extremities, ears, nose, and cheeks; this may be followed by gangrene. Pain, depression, stiffness, and congestion follow; stupor, coma, and death may supervene.

Post-mortem appearances: The skin is pale and waxy, with irregular dusky, reddish patches; the superficial parts are bloodless, while the viscera, including the brain, are congested; the heart and large vessels leading from it are

full of blood, and the blood is of a brighter red color than usual.

5. The poisonous action of coal gas depends upon the presence and action of carbon monoxide. This carbon monoxide unites with the hemoglobin of the blood, forming a very stable compound, which is not oxidized in the lungs; thus internal asphyxiation is produced.

MATERIA MEDICA AND THERAPEUTICS.

1. The official soluble salts of iron are: Ferri sulphas, ferri chloridum, ferri et ammonii sulphas, ferri phosphas solubilis, ferri et potassii tartras, ferri et ammonii citras, ferri et strychninæ citras, ferri et ammonii tartras, ferri citras, ferri et quininæ citras, ferri et quininæ citras solubilis, ferri pyrophosphas solubilis.

3. R. Acidi salicylici, ʒiijss.
Ammonii carbonatis, gr. lxxij.
Spiritus menthæ piperitæ, ♏v.
Glycerin, ʒiv.
Aquæ distillatæ, q.s. ad ʒiij. M.
Sig: One teaspoonful every three hours.

4. The average adult dose of the following:
(a) Arsenous acid, gr. 1/30.
(b) Fl. ext. Cannabis Indica, ♏ jss.
(c) Ext. hyoscyamus, gr. j.
(d) Heroin hydrochlorid, gr. 1/10.
(e) Hydrocyanic acid dilute, ♏ jss.
(f) Tr. aconite, U. S. P., ♏ x.
(g) Lead acetate, gr. jss.
(h) Guaiacol carbonate, gr. xv.
(i) Sulphonal, gr. xv.
(j) Acetanilid, gr. iv.

PATHOLOGY.

2. The three main factors recognized as causing hemophilia are: (1) Hereditary predisposition transmitted through the female line, (2) male sex, and (3) early life. Of course, there must be a trauma as the exciting cause.

BACTERIOLOGY.

1. The five nutrient media commonly employed in the culture of pathogenic bacteria are: Bouillon, gelatin, agar-agar, blood-serum, and potatoes.

3. The bacteria that may be found in a *phlegmon* are: *Streptococcus pyogenes*, and sometimes some of the following: *Staphylococcus pyogenes aureus, Staphylococcus pyogenes albus, Staphylococcus pyogenes citreus, Micrococcus tetragenus, Bacillus pyocyaneus.*

In a *cold abscess* there may be the *Bacillus tuberculosis*, and occasionally a few of those just named.

4. In *actinomycosis* the microscopical findings include the actinomyces, round cell infiltration with granulation tissue, and cicatricial bands; much connective tissue is produced. There are small granulation tumors consisting of giant cells, epitheloid cells, and small round cells.

5. Take a small particle from the sputum or other material and smear it on a slide, making the smear as thin as possible. Then cover it with some carbolfuchsin, and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods, while all other bacteria will appear blue.

MEDICINE.

1. Apoplexy (cerebral hemorrhage) must be differentiated from the coma of opium, of alcoholism, of uremia, of epilepsy, of hysteria, of diabetes.

2.

PERICARDIAL EFFUSION.	ENLARGED HEART.
Area of dullness is pear-shaped and the enlargement is chiefly upward.	Area of dullness is not pear-shaped, and the enlargement is chiefly downward.
Dullness may extend to left of apex-beat.	Dullness does not extend to left of apex-beat.
Generally rapid development.	Usually slow development.
Apex-beat is feeble or lost.	Apex-beat is generally apparent, and may be powerful.
The heart sounds are not clearly heard.	The heart sounds are generally clearly heard.

3. *Leukemia* is a condition in which the white blood corpuscles are increased in number, and is accompanied by pathological changes in the spleen, lymphatic glands, and bone marrow.

8. *Measles.* Period of incubation, ten to twelve days. Stage of invasion, four days. Character of eruption, small dark red papules with crescentic borders, beginning on face and rapidly spreading over entire body; desquamation is branny.

Scarlet fever. Period of incubation, from a few hours to seven days. Stage of invasion, twenty-four hours. Character of eruption, a scarlet punctate rash, beginning on neck and chest, then covering face and body; desquamation is scaly or in flakes.

9. There may be periostitis, osteitis, gummata, necrosis, tenderness, osteoscopic pains, and sometimes ulceration.

SURGERY.

1. *Normal salt solution. Composition*: 0.7 per cent of sodium chloride in sterilized water. Chemically speaking, it is practically a decinormal solution.

Preparation: It is made by putting one and a half drachms of sterilized salt in a quart of distilled water in a glass flask. The mouth of the flask should be plugged with sterilized cotton.

Uses: Intravenous injection or infusion, irrigation of fresh wounds, removal of blood or foreign bodies, cleansing of mucous or serous surfaces.

4. *Pathology of acute osteomyclitis*: "When exposed to septic infection the marrow in long bones is only too favorably placed for the diffusion of violent inflammation. Confined within a rigid shell, and in free communication from end to end by its abundant blood and lymph vessels, the medullary tissue, when inflamed, suffers double disaster from the rapidity of the spread of the inflammation, and the impossibility of relief by swelling. Its soft sensitive tissues are strangulated by their own proliferation, and the bone, cut off from its most important blood supply, suffers death. In the compact bone the incompressible veins may serve to carry infection to the system, and fatty embolism from a similar source is not unknown.

"The naked-eye appearances of a bone affected with acute osteomyelitis are striking and characteristic. The compact tissue is pink generally, or in patches; the cancellous bone is of a bright or dusky red color, and the marrow is transformed into a semifluid, often stinking material, made up of pus and diffluent fat, and exhibiting red streaks and patches representing injected vessels and extravasated blood. In some cases, especially in the non-traumatic variety, a subperiosteal abscess forms. This is usually found where the compact bone is thinnest, and its foramina most numerous; that is to say, above the epiphyses, near the joint. In this situation suppurative inflammation of the epiphysial cartilage is peculiarly liable to take place, leading to disjunction of the epiphysis from the shaft, and producing the condition known as 'acute epiphysitis.'

"The usual termination of those cases which do not rapidly prove fatal from general septic infection, is in necrosis of the whole bone, or, more frequently, of the shaft between the epiphyses. The further history of the disease is then simply that of necrosis of bone.

"The minute anatomy is a compound of cellular proliferation, vascular blocking, diffluence of fatty tissue, and general infiltration with microorganisms. The bony tissue proper, suddenly cut off from its nutritive supply and rapidly dying, has had no opportunity of exhibiting the signs of inflammation and is essentially unchanged." (Treves' *Manual of Surgery.*)

6. In the great majority of cases no differential diagnosis can be made between *gastric* and *duodenal ulcer.* But (1) sudden and recurring intestinal hemorrhage of sufficient severity to produce anemia, (2) pain in the right hypochondriac region, coming on two or three hours after eating and (3) violent gastric crisis of pain, are supposed to be indicative of *duodenal* ulcer.

7. In *nephrolithiasis* there is more likely to be hemorrhage.

In *nephrophthisis* the tubercle bacilli will be found in the urinary sediment, and a focus of tuberculosis will be found somewhere.

Catheterization of the ureters will determine on which side the lesion exists.

9. "The pterygium may be dissected away with a sharp scalpel or Beer's knife, and cut off, the conjunctival defect being closed by uniting the upper and lower borders, undermining the conjunctiva if necessary to bring the edges together. The apex of the pterygium must be thoroughly excised from the cornea, and its attachment in this situation scraped or cauterized with the actual cautery, to prevent recurrence. Instead of cutting off the pterygium, it may be dissected up and stitched underneath the detached conjunctiva, either above or below; or it may be divided into two halves, of which one is transplanted above and the other below, being held in the conjunctival pocket by a stitch." (May's *Diseases of the Eye.*)

10. "Immediately after the injury, absolute rest, iced compresses, and atropine are to be employed. If the rapid swelling of the lens causes inflammation or much increase of tension, the cataract should be removed by extraction. But if such complication do not arise, it is wiser to allow absorption to proceed, and to defer operative intervention until there is no irritation or inflammation, and spontaneous improvement has come to a standstill." (May's *Diseases of the Eye.*)

OBSTETRICS.

1. The true pelvis is bounded *above* by a plane passing through the iliopectineal line; in *front* by the pubic bones and the obturator membrane; *behind* by the concavity of the sacrum; *laterally* by the obturator membrane, the sacrosciatic ligaments and the internal surface of the acetabulum.

The *brim* is the edge of the superior strait of the pelvis. The *false pelvis* is that part of the pelvis situated above the superior strait.

DISEASES OF WOMEN.

3. Uterine hemorrhage, independent of menstruation or pregnancy, generally denotes some form of new growth (polypus, fibroid, sarcoma, or carcinoma) of the uterus or cervix; it may also be due to some injury, either during coitus or as the result of some accident.

4. Trachelorrhaphy is indicated in cases of lacerated cervix in which the loss of tissue is but slight, and there is no cystic degeneration or induration.

5. *Painful defecation* is a prominent symptom in: Prolapsed and cystic ovary, pelvic cellulitis or abscess, inflammation of tubes or ovaries, and retroflexion or retroversion of the uterus.

Bearing-down feeling is a prominent symptom in: Prolapsed uterus, badly lacerated perineum, cystocele, rectocele, hyperplasia of cervix, inversion of the uterus, foreign body in the vagina.

Leucorrheal discharge is a prominent symptom in: Pelvic congestion, endometritis, retroversion of uterus, vulvitis, vaginitis, gonorrhea, benign and malignant growths.

INOPERABLE SARCOMA. A FURTHER REPORT OF CASES SUCCESSFULLY TREATED WITH THE MIXED TOXINS OF ERYSIPELAS AND BACILLUS PRODIGIOSUS.

By WILLIAM B. COLEY, M.D.,

NEW YORK.

ATTENDING SURGEON TO THE GENERAL MEMORIAL HOSPITAL; ASSOCIATE SURGEON TO THE HOSPITAL FOR RUPTURED AND CRIPPLED.

At the meeting of the Surgical Section of the New York Academy of Medicine on May 3, 1907, I presented six patients who had been successfully treated with the mixed toxins of erysipelas and bacillus prodigiosus for inoperable sarcoma. All of these cases were practically hopeless, as far as cure by any other known method of treatment was concerned. Three of these patients were well from five to eleven and a half years after treatment. In every case a careful microscopical examination had been made by the highest authorities in pathology in America.

In addition to the histories of these six cases it seemed not out of place to give a very brief summary of the present status of the treatment of inoperable sarcoma with the mixed toxins of erysipelas and bacillus prodigiosus.

Although the final results of my work with the toxins were published in the *American Journal of the Medical Sciences*, in March, 1906, the great majority of medical men are still uninformed of what the mixed toxins of erysipelas and bacillus prodigiosus really are, and ignorant of the results that have been obtained by their use in the treatment of hopeless, inoperable cases of sarcoma. For a detailed account of the development of the early method, the reader is referred to the paper above mentioned.

My original experiments, carried out in 1891 and 1892, with the cooperation of Dr. William T. Bull (*Amer. Jour. Med. Science*, 1893), with twelve cases of inoperable sarcoma and carcinoma, in which I used the living cultures of erysipelas, form the inspiration and basis of the toxin method. From these twelve cases I learned two things: (1) That it is most difficult to produce erysipelas when desired; (2) that when produced there is considerable danger of the patient's dying of the attack, two of the twelve cases having succumbed to the artificially-produced erysipelas. In four cases I was unable to produce an attack, although I made many attempts. Repeated injections with the living cultures of erysipelas, however, showed a distinct inhibitory action upon the growth of the tumor, but this action was never sufficient to cause entire disappearance of the tumor, and was usually but temporary in character. This experience led me to try sterilizing the cultures by heat, which, of course, eliminated the risks associated with the actual attack of erysipelas. I found that the inhibitory action was apparently equally marked whether the cultures were living or dead, yet insufficient to completely control the tumor growth. At about this time I read of Roger's experiments in Paris, in which he stated that by growing Bacillus prodigiosus with the streptococcus of erysipelas, the virulence of the latter was greatly increased. Roger's experiments were confined entirely to rabbits, and, as far as I know, the use of the prodigiosus had never been suggested as a therapeutic measure in the human being. In the latter part of 1892 I began using the mixed toxins, first prepared by Dr. Alexander Lambert, but since 1893, by Dr. B. H. Buxton, now professor of experimental pathology at Cornell University. At first the erysipelas streptococcus was grown alone in bouillon for about twelve days; then the Bacillus prodigiosus was added, and the two cultures were grown together for ten days longer, at the end of which time they were sterilized by heat of 60° C. and preserved by the addition of thymol crystals. Efforts were made to secure streptococcus from either a fatal case or some very virulent source. The toxins which I have used up to a year ago were prepared by Dr. Buxton in the way described; none of my successful cases were treated with the erysipelas toxins alone. In the beginning I used filtered cultures for a few months, but the reactions following the injections were so weak that I soon decided to use the entire cultures, only sterilized by heat, thus utilizing the toxins contained in the dead bodies of the bacilli as well as those that were soluble. The results at once showed a striking improvement over those obtained with the toxins prepared from the streptococcus alone. During the last few years I have reached the conclusion that the bacillus prodigiosus plays a far more important part than I had hitherto believed. I had often noted that in the preparation in which the red color of the bacillus prodigiosus was nearly absent, or quite faint, the strength of the toxins was much inferior, and the destructive effect upon the tumor was correspondingly diminished. From the very red toxins, showing a large amount of bacillus prodigiosus I had the best results.

The truth of my conclusions that the bacillus prodigiosus has an actual, curative value of its own, aside from the effect it may have in increasing the virulence of the streptococci of erysipelas, has recently been verified by Dr. Martha Tracy, of the Laboratory of the Huntington Cancer Research Fund. (*Journal of Med. Research*, Vol. XVI., No. 2, 1907.) She has been conducting, during most of last year, a series of investigations into the chemical and biological nature of the bacillus prodigiosus and the mixed toxins, and has found the toxins of the bacillus prodigiosus to be one of the most powerful known in bacteriology. This opinion has already been expressed by Prof. Vaughan of Ann Arbor, Mich. Dr. Tracy has studied the effect of the toxins of the streptococcus alone, of the bacil-

*Read before the Hartford Medical Society, May 27, 1907; with reports of cases presented to the Surgical Section of the New York Academy of Medicine, May 3, 1907.

lus prodigiosus alone and of the combined toxins, upon sarcoma in dogs, and she has established the most important fact, that the bacillus prodigiosus alone has the power of causing the entire disappearance of rapidly growing sarcomas in dogs and their apparent cure. She has, furthermore, found that the mixed toxins of erysipelas and bacillus prodigiosus caused even a more rapid disappearance of the tumors than the bacillus prodigiosus alone.

Thus, we have experimental proof of the curative action of the bacillus prodigiosus alone upon sarcoma, entirely confirming my own clinical observations of sarcoma in man.

Furthermore, Dr. Tracy has found that the curative action of the toxins is brought about by increased leucocytosis and coagulation necrosis—precisely the explanation of the action of the toxins which I published nearly fourteen years ago. Dr. Tracy has seen a sarcoma, half the size of a hen's egg, in a dog, become necrotic and entirely disappear under one or two injections with the mixed toxins, exactly as happened with an inoperable metastatic sarcoma of the iliolumbar region, the size of a child's head, in the case of a periosteal sarcoma of the femur which I presented to the Surgical Section of the Academy, well five years, and the history of which is here appended.

(The results of Dr. Tracy's experiments were reported before the Section on Pathology at the recent meeting of the American Medical Association.)

In view of Dr. Tracy's experimental demonstration of the important and independent part played by the bacillus prodigiosus in the curative process it occurred to her that the way to standardize the preparation and make it possible to estimate more accurately its strength and dosage, would be, to grow the two organisms separately, reduce the bacillus prodigiosus to a dry powder, add so many milligrams by weight per cubic centimeter to the sterilized streptococcus broth. Her process in detail is as follows:

Streptococcus culture in broth—three weeks' growth	100 c.c.
Prodigiosus suspension, containing 750 milligrams of prodigiosus proteid	30 c.c.
Glycerin	20 c.c.

Each cubic centimeter of the mixture then contains 5 milligrams of the prodigiosus proteid. Considering 1 oz. to be equal to 29.57 c.c., it contains 147.85 milligrams prodigiosus proteid; 1 c.c. equals about 17 minims, so 1 minim contains about 3 milligrams of prodigiosus.

The prodigiosus suspension used is made and measured in the following way: Prodigiosus is grown on agar for ten days. There is then a thick red growth, which is scraped off with glass rods and rubbed up with a mortar and pestle to a smooth, rather thick suspension, using physiological salt solution as diluent. This suspension is sterilized by heat—one hour at 75°. The total nitrogen per c.c. is determined and the weight of nitrogen per c.c. multiplied by the factor 6.25 gives the weight of proteid present. Thus the weight of prodigiosus proteid in each c.c is known and the suspension is diluted to the required strength before mixing with the streptococcus culture. After mixing and bottling the toxins, the mixture is again sterilized two hours at 75°.

The toxins made in this way I have used almost exclusively during the past six months, and I believe that they are not only more powerful than the eosin preparations but more efficient.

A word of warning should be said in regard to the dangers attending the use of such a powerful preparation as the mixed toxins. If proper precautions are observed, I believe the toxins may be used with almost perfect safety. In about 400 cases in which I have used the mixed toxins during the last fifteen years there have been only three cases in which death could, possibly, be attributed to the injections. All three of these cases were in the last stages of the disease, suffering from extensive metastases, associated with very feeble heart action. Two of the cases presented extensive involvement of the mediastinal glands. In both of these cases the treatment had only just been begun for two or three days and sufficient doses had not been given to produce any marked reaction. The patients died suddenly, apparently as a result of an embolus. There has been a recent doubt in the case of an enormous sarcoma of the thigh. Within ten days after beginning the treatment the patient died of acute infection with the gas bacillus (aërogenes capsulatus) from some unknown source. The preparation of toxins was perfectly sterile I had seen the patient but did not personally treat him.

It is most important to begin in every case with a very small dose, not over ¼ minim (diluted with a little boiled water to insure accuracy of dosage). If the tumor in question is highly vascular, it is wiser to begin the injections remote from the same, until the susceptibility of the patient to the toxins has been ascertained. This varies considerably in different individuals. After a few doses it is safe, in most cases, to inject into the tumor itself.

As a rule, when giving injections into the tumor, only about one-fifth of the dose used for injections remote from the tumor is required to produce the same reaction. The dose should be increased by ¼ minim when given into the tumor; by ½ minim when injected remote from the tumor, until the desired reaction is obtained. The best results are obtained by doses sufficiently large to produce severe reactions, say a temperature of 102° to 105°.

The frequency of the injections must depend entirely upon the strength of the patient, some being able to bear daily injections, while in others it may be unwise to push the treatment beyond three or four injections a week.

In the successful cases the effect is usually very promptly noticeable. The tumor becomes smaller in size, much more movable, and very much less vascular. These changes appear very quickly, often within two to three days.

The action of the toxins is both local and systemic. Sometimes the best results are obtained by giving the injections alternately into the tumor and remote from the same. In tumors in inaccessible regions, *e.g.* intraabdominal sarcoma, or sarcoma of the tonsil, a perfect cure may be obtained entirely by systemic injections.

Some twelve years ago, when I published my early cases successfully treated with the toxins (Transactions of the Amer. Surg. Assoc., 1894), it was but natural that there should be attempts made to explain these successes by every possible means, rather than admit that a new agent had been discovered that actually caused the disappearance and apparent cure of an inoperable malignant tumor. In view of the innumerable claims that have been and are still being constantly put forth in behalf of new remedies for the cure of cancer, it is well that there exists such deep-rooted skepticism on the part of the medical profession, and unless a new remedy can overcome this skepticism and can successfully meet every test known to scientific medicine, it should be allowed to die a natural death and take its place among the

other remedies that have had their ephemeral existence and are now resting in quiet oblivion. For this reason, a considerable period of time—several years at least—must necessarily elapse as a trying-out period of any new remedy for malignant tumors, in order that every chance for error of diagnosis may be eliminated and that the after-history of patients supposed to have been cured, may be carefully traced to determine whether the cure has been temporary or permanent.

In the case of the mixed toxins, which I have now been using since 1892, it would seem that the testing period had been sufficiently long for us to be able to determine in an impartial and judicial way the value of the method. The early successes were explained away on the ground that there must have been an error in the diagnosis; and if only one or two or three successes had been obtained such explanation would be right and proper, but, as time has gone on, other successes have followed, and these have now reached such numbers (I have had 42 personal successes and there have been nearly 100 in the hands of other surgeons) that, to explain them as errors of diagnosis or as cases of spontaneous disappearance would be neither a judicial nor a scientific disposition of the problem. These cases have in nearly every instance been diagnosticated as sarcoma by the leading surgeons of America, they have not been cases seen in the early stage of the disease, in which the diagnosis is often difficult, but were all far-advanced, inoperable cases, entirely hopeless from any other method of treatment. In nearly every case careful microscopical examination was made by the most expert pathologists of the land, including Professors Wm. H. Welch of Johns Hopkins, W. T. Whitney of the Massachusetts General Hospital, James Ewing of Cornell, Hy. T. Brooks of the Post-Graduate Hospital, T. Mitchell Prudden of Columbia, and John T. Caven of the University of Toronto.

Furthermore, in many cases a history of local or general recurrence following a previous operation has rendered the diagnosis as nearly absolute as would seem possible; and yet there is one other fact that carries us a step further and establishes the diagnosis beyond any possible doubt, and that is the fact that in several of these cases in which the tumor disappeared under the toxin treatment and the patient remained well for several years, there followed a recurrence of the trouble which finally caused death. We must admit in these cases that the toxins caused the entire disappearance of an inoperable tumor, clinically and microscopically sarcoma, which finally returned and caused the death of the patient. Is it not much more rational, then, and more scientific to grant that in the other cases in which the tumors, clinically and microscopically sarcoma, disappeared under the influence of the mixed toxins, were likewise actually and truly sarcoma, rather than to attempt to explain them away as errors in diagnosis?

There are some men who attempt to explain the successful cases on the ground that they were syphilitic tumors, rather than sarcoma. But a careful study of these cases, the clinical features of the tumors, the history of local or general recurrence after operation, combined with the microscopical examinations by the highest authorities in pathology, would seem to leave such explanation without any reasonable basis. If the cases of cures were confined to round-celled sarcoma, which, on microscopical examination, does sometimes closely resemble syphilitic lesions, there would be some slight ground for this opinion, but the type of sarcoma that has shown the best results from the treatment has been the spindle-celled, which is practically never confounded with syphilitic growths. The history of one of my cases has an important bearing in this connection:

Case I.* *Inoperable Spindle-celled Sarcoma of the Abdominal Wall and Pelvis Treated with the Mixed Toxins of Erysipelas and Bacillus Prodigiosus from December, 1892, to June, 1893; Entire Disappearance, Patient Well at Present, Fourteen Years Later.*—J. F., aged sixteen years (at the time the treatment was begun), suffering from a large tumor involving the lower portion of the abdominal wall, attached to the bladder and pelvis. The patient, who was confined to his bed and had lost considerable weight, was referred to me by Dr. L. Bolton Bangs, in December, 1892, as a totally hopeless, inoperable case. A portion of the tumor was removed for microscopical examination, and was pronounced spindle-celled sarcoma by Dr. H. T. Brooks, pathologist at the Post-Graduate Hospital. He received injections with the mixed toxins of erysipelas and bacillus prodigiosus from December, 1892, to June, 1893. At the end of this time the tumor had entirely disappeared. The patient received no further treatment and has remained perfectly well up to the present time. I presented him before the meeting of the New York Surgical Society in November, 1906.

This case, in addition to representing my oldest cure (well fourteen years) is of peculiar interest from another standpoint, *i.e.* the theory of possible syphilitic origin. The age of this patient was sixteen years at the time the treatment was begun; there was absolutely no history nor evidence of congenital syphilis. Six to seven years after the tumor had disappeared in this case and the boy had grown up into manhood, he contracted a typical primary lesion of syphilis, for which I treated him and which ran the usual course, practically proving that his original tumor of the abdominal wall and pelvis which had disappeared six years before under the toxin treatment, was really spindle-celled sarcoma, as shown by the microscope, and not a syphilitic growth. If we are to explain away the toxin cures in this way, it is clearly only fair to apply the same rule to the cures following operations.

Aside from the criticism and skepticism that any new method must undergo and should be glad to meet, there is another kind of skepticism that has long been characteristic of the medical profession, and which still exists, though perhaps in a less pronounced degree than in former years. As one of the most striking examples of this type, I will cite the early experience of Oliver Wendell Holmes in his attempt to prove the contagiousness of puerperal fever, in 1843. With a great deal of labor Holmes had collected from original sources here and abroad such a mass of evidence in support of the opinion that puerperal fever was a contagious, communicable disease, that it seemed impossible that any man capable of simple thinking and of sufficient independence to have an opinion of his own could fail to be convinced. And yet, what was the result? Nine years after the publication of Holmes' elaborate paper, we find two of the leading professors of obstetrics in America, Hodge and Meigs of Philadelphia, do their utmost to controvert the proven thesis of Holmes. To quote from their own words: "The result of the whole discussion will, I trust, serve not only to exalt your views of the value and dignity of our profession, but to divest your minds of the overpowering dread that you can ever become, especially to woman,

*This patient was to have been presented at the meeting on May 3, 1907, of the Academy of Medicine, but was detained by business matters.

under the extremely interesting circumstances of gestation and parturition, the minister of evil; that you can ever convey, in any possible manner, a horrible virus, so destructive in its effects, and so mysterious in its operations as that attributed to puerperal fever." (Prof. Hodge, 1852.)

"I prefer to attribute them to accident, or Providence, of which I can form a conception, rather than to contagion of which I cannot form any clear idea, at least as to this particular malady." (Prof. Meigs, 1852.)

As in the times of Holmes, there are still many medical men who "are not satisfied with proof. They cannot believe a point is settled so long as everybody is not silenced."

Such has been the type of skepticism the toxins have had to meet. Yet there is increasing evidence within the last two years that the end of such skepticism is drawing near, and the profession are beginning to appreciate the fact that the method has an important place in the treatment or sarcoma. This method is not a substitute for operation, and there is no stronger advocate than I, of early and thorough surgical treatment of every type of malignant tumor that is not too far advanced for operation. But after all that has been done that surgery can offer, there remains at least 75 per cent. of malignant tumors in which the disease is either too far advanced for operation when first seen by the physician, or which have recurred after operation and are no longer removable by surgical means. It is in this class of cases, the most pitiable of all that come to us for aid, that we must look beyond surgery for means to help. That we cannot cure all such cases is no reason we should refuse to save the few that it has been shown possible to save by the use of the mixed toxins. That we can save from 10 to 15 per cent. of such otherwise hopeless cases of inoperable sarcoma, has been demonstrated, and there is reason to hope that further investigation along the lines of preparing the toxins, together with greater experience in their administration, will enable us to obtain far better results.

In addition to employing the mixed toxins in cases of strictly inoperable sarcoma, I have, recently, advocated their preliminary use in sarcoma of the long bones, before sacrificing the limb, and the limb has been saved in a sufficient number of such cases, I think, to justify the wisdom of this course. (Sarcoma of the Long Bones, with a Report of 68 Cases. *Annals of Surg.*, March, 1907.)

Up to the present time I have been able to collect twelve cases of sarcoma of the long bones, three personal cases and nine reported by other physicians, in which the use of the toxins has rendered amputation unnecessary. In eight of these cases the sarcoma was of the round-celled variety, in two spindle-celled, and in the remaining two no microscopical examination was made, but amputation had seemed the only means of saving the patient's life.

Eight of these cases remained alive and well and free from recurrence from three to eight years; one for two years; one for one year; two for less than six months.

The seat of the disease in these cases were as follows: Tibia, six; fibula, one; femur, three; radius, one; humerus, one.

There is a new field for the use of the toxins in which, I believe, the results will far surpass anything that has hitherto been accomplished in inoperable sarcoma; that is, their employment after all primary operations for sarcoma, and possibly carcinoma, as a prophylactic against recurrence. While up to the present time the data are not sufficient to amount to absolute proof of the wisdom of such a course, they certainly furnish very strong reasons in its favor. Theoretically it would seem rational to assume that, if the toxins exert an inhibitory or destructive action systemic in character sufficient to cause the disappearance and permanent cure of large, inoperable tumors, they would be much more likely, when given after primary operations, to destroy the few cells that were left behind after such an operation, and which form the basis of recurrence which follow in at least two-thirds of all cases.

The practical grounds in favor of adopting this plan are that in about twenty-five cases in which I have myself carried out such prophylactic treatment the number of recurrences has been extremely small. A number of other surgeons are already using the toxins in this way.

When used as a prophylactic measure, it is unnecessary to give the large doses that one must use in cases of inoperable sarcoma; the patient need not be confined to the bed and may pursue the regular routine of life; only sufficiently large doses should be used to cause a slight rise of temperature, say 99° to 100°, repeated three or four times a week. It is impossible to state how long such treatment should be carried out. My own plan has been to give two or three periods of treatment from four to six weeks in duration. I believe the treatment given in this way is devoid of danger, and think it will cut down the number of recurrences by more than one-half.

The following histories include those of patients presented before the New York Academy of Medicine, Surgical Section, May 3, 1907. Cases II. to VIII. were shown at this time.

Case II. *Sarcoma of the Pectoral Region (Breast and Axilla) Cured by the Mixed Toxins; Well Eleven Years.*—Miss E. F., aged forty-two years. Grandmother died of cancer of the breast. Has always been well. She first noticed a lump in the outer border of the left axilla, extending upwards to the supraclavicular region, in October, 1895. This grew very rapidly until it reached the size of a small orange; it was firmly adherent to the deep parts and extended around into the axilla and involved a portion of the breast. By December 15, 1895, it had become so firmly adherent to the axillary fascia that on consultation, Drs. Storrs and Knight of the Hartford Hospital decided it to be entirely inoperable. An exploratory incision was made and a portion of the tumor removed by Dr. R. H. Griswold, who pronounced it a spindle-celled sarcoma. A section was sent to me and I had the diagnosis verified by Drs. E. K. Dunham and Buxton, pathologists to the New York Cancer Hospital, and finally by Dr. W. H. Welch of Johns Hopkins, all of whom agreed that it was spindle-celled sarcoma. The treatment with the mixed toxins was immediately begun under my direction by Dr. R. H. Griswold, the associate of Dr. Storrs. The tumor immediately began to show improvement and the patient soon began to gain weight which had fallen off twenty-four pounds since the tumor was discovered. The injections were given four or five times a week in the neighborhood of the tumor and the treatment was continued until seventy-eight injections had been given. At the end of this period the tumor had entirely disappeared and the patient had recovered her normal health. I presented her before the New York Surgical Society eleven months later, in 1896, and she has remained well up to the present time eleven and one-half years after the disappearance of the growth.

Case III. *Round-celled Sarcoma of the Tonsil and Nasopharynx with Metastases in the Neck; Disappearance under the Mixed Toxin Treatment; Re-*

currence a Year Later.—W. C. C., forty-two years of age, shoemaker, born in New Hampshire. Father died of cancer of the liver. In January, 1906, the patient noticed a lump on the right side of the neck, under the angle of the jaw; at about the same time he noticed a swelling in the right side of the pharynx, behind the tonsil. Both tumors increased in size rapidly. Two months later a similar tumor appeared in the left side of the neck. He never had any pain. The patient soon began to lose weight rather rapidly. He also began to notice difficulty in talking clearly. This was apparently due to an obstruction in the nasopharynx. He was referred to me on May 29, 1906, by Dr. T. J. Reardon, a throat specialist of Boston. Physical examination at this time shows a tumor the size of a goose egg, extending from the angle of the jaw on the right side to the mastoid process. The tumor is smooth in outline, not infiltrating the surrounding tissues, skin not adherent, and of about the consistence of a round-celled sarcoma. A similar tumor is present on the left side, though not quite so large. On the right side of the throat anteriorly to the tonsil is a mass extending up to the uvula and nasopharynx, moderately firm in consistence and not ulcerated. Clinical diagnosis: Round-celled sarcoma. The patient's general condition showed considerable loss of weight and beginning emaciation. My prognosis was so bad that I did not think it worth while even to take a specimen for microscopical examination, although I had a photograph taken. He entered the General Memorial Hospital on May 29, 1906, and was discharged on July 9. He was immediately put upon the mixed toxins of erysipelas and bacillus prodigiosus, the injections being made alternately into the tumors of the neck and the pectoral region. The initial dose was ½ minim; this was gradually increased until he received 14 minims in the neck and 22 minims in the pectoral region. Very severe reactions resulted, the temperature ranging between 103° and 105°. After two weeks' treatment there was marked softening and decrease, both in the tumors of the neck and tonsil. The treatment was pushed to the utmost limits that his strength would endure and, naturally, his loss of weight continued. On July 9, after he had had thirty-one injections in all, I advised his going home for a period of recuperation. At the time he left the hospital, although there had been considerable decrease in the size of the tumors and marked softening, I did not believe there was any reasonable hope of final success. After his return to Boston the softening continued, especially in the nasopharyngeal tumor, and he had several very severe hemorrhages, losing as much as a pint of blood at a time. He saw a surgeon in Boston, who first recommended ligation of the external carotids, but finally decided that his general condition was too low to warrant the operation. Aside from prayer treatment and some patent medicines which he took internally and which may have contained iodide of potassium, nothing further was done until the latter part of September, 1906, when he again consulted Dr. Reardon, after which the latter wrote me as follows: "You probably remember the patient I sent to you some four or five months ago, Mr. C. I have seen him to-day and the result is simply miraculous. He presents no glandular swelling at all on the left side; on the right side there is some swelling about the subcutaneous tissues over the sternocleidomastoid muscle where you injected the toxins. The punctures are still surrounded by a slight bluish-red area. The throat is practically free from all swelling, except on the right side the mucous membrane posterior to the posterior pillar of the fauces presents a whitish, flabby appearance, but there is no mass behind it. The roof of the pharynx is absolutely free from all signs of the growth." A few weeks later all evidence of the swelling, even on the left side, disappeared and the patient has remained well up to a few weeks ago.

Although when seen by Dr. Reardon as well as myself and my colleagues at the hospital, Drs. Dowd and Downes, there was absolutely no doubt in our minds that the tumors were sarcoma, we still regretted the fact that no microscopical examination had been made to establish absolutely the character of the growths. Unfortunately for the patient, but fortunately for the scientific value of the case, a few weeks ago, there was a recurrence on the left side of the neck, a little above the tumor that had disappeared under the toxin treatment. This slowly increased in size, and the patient came to me about two weeks ago, presenting a tumor about the size of a hen's egg under the left angle of the jaw, smooth in outline, not adherent to the skin, semi-fluctuating in consistence. There was absolutely no return of the disease on the right side or in the pharynx. He was admitted to the General Memorial Hospital and Dr. Downes made an incision over the tumor and found it had broken down in the center and more or less infiltrated the periosteum of the jaw. The tumor was removed as far as possible, although there was considerable left behind. Microscopical examination showed it to be *small round-celled sarcoma.* The patient has again been put upon the mixed toxins and the treatment will be continued for a number of weeks.

In view of the recurrence and microscopical examination there can be no longer any doubt that the primary growth was sarcoma, and, considering the extensive involvement of the same with large metastases in both sides of the neck, it certainly represents one of the most remarkable cases that have yet been recorded.

Case IV. *Round-celled Sarcoma of the Ulna.*—J. D. S., twenty-five years. Family history good. On December 8, 1898, Dr. Geo. Tully Vaughan amputated the right arm in the lower third for sarcoma of the ulna. The patient at that time gave a history of having a "greenstick" fracture of the right ulna three years before, from which he recovered. This case I have reported fully in a recent paper on Sarcoma of the Long Bones (*Annals of Surgery*, March, 1907) and will give only a brief résumé.

After the amputation the patient made a good recovery and remained well until February, 1906, when he noticed an increase in the size of his abdomen, but had no pain and paid no attention to it. In the beginning of October, pain developing, he consulted Dr. J. W. Perkins of Kansas City, Mo., who referred him to me. Physical examination, October 29, showed the right arm absent, no local recurrence nor evidence of a return of the disease in the axilla. Examination of the abdomen showed the same markedly protuberant, but symmetrically enlarged. Palpation showed the abdomen filled with an enormous tumor, extending from the ensiform cartilage nearly to the symphysis pubis; the intestines being pushed over to the left side. Several large masses, each the size of a child's head, more or less independent from one another, could be made out. They seemed to start in the retroperitoneal glands, involving the mesentery and omentum; no ascites.

The patient was put upon the mixed toxins in November, 1906, with little hope of doing him much good, but at the end of one month's treatment there was a marked decrease in the size of the tumors and the circumference of the abdomen had steadily di-

minished. The treatment has been continued up to the present time, with several periods of rest from three to four weeks in duration. The patient has regained his normal health and the circumference of his abdomen has decreased over five inches. The masses in the abdomen are much more discreet and more movable.

Case V. *Small Round-celled Sarcoma of the Neck and Tonsil; Entire Disappearance in Seven Weeks under Treatment with the Mixed Toxins.*—H. M., aged thirty-two years; harness-maker by occupation; family history good. The patient was referred to me on October 17, 1905, by Dr. Arpad G. Gerster of New York as an inoperable case of recurrent, small round-celled sarcoma. The patient gave the following history: In about the middle of August, 1905, he noticed a swelling on the left side of the neck, just behind the sternomastoid muscle. At about the same time he also noticed an enlargement of his left tonsil; there was no pain at first, but as both tumors increased rapidly in size they soon became painful. In the latter part of August, 1905, the patient was operated upon at St. Mark's Hospital by Dr. Carl Beck, who made an attempt to remove the tonsil tumor, as well as that of the neck; he found it impossible, however, to make a complete excision. The patient was immediately put upon the *x*-ray treatment every other day, and also received radium treatment externally and internally; the latter, however, had little, if any, influence in checking the rapid growth of the tumor. On October 13, while under the care of Dr. Goldwater at the New York Polyclinic, a portion of the tonsil tumor was removed and examined by Dr. F. M. Jeffries, director of the Pathological Laboratory of the New York Polyclinic, and also by the Pathologist of the Practitioners' Laboratory, both of whom reported the tumor to be a small round-celled sarcoma. On October 17, the time that I first saw the patient, physical examination showed the following condition: The left side of the neck was occupied by a globular tumor, about the size of half an orange; it extended from the angle of the jaw in front to the mastoid process behind and downwards nearly to the clavicle. Its consistence was about the same as that ordinarily found in round-celled sarcoma; the skin was not adherent. Examination of the left tonsil showed it enlarged to two to three times its normal size. The patient's general health had been but little affected. He was admitted to the General Memorial Hospital on October 17, 1905, and immediately put upon the mixed toxins of erysipelas and bacillus prodigiosus without any other treatment. Daily injections were given, alternating, one day into the tumor direct, the other, into the pectoral region. The highest dose given was seven minims; his temperature ranged between 99.5 and 103°. In less than a week there was decided decrease in the size of the tumor and increase in mobility. The diminution continued steadily until, at the end of six weeks, both the cervical and tonsil tumors had apparently entirely disappeared. The patient was shown before a meeting of the Harvard Medical Society on November 25, 1905, and before the New York Surgical Society in January, 1906. He left the hospital at the end of seven weeks, and, although there were no visible remains of the tumor, the toxins were kept up twice a week in the pectoral region for about three months as a prophylactic against further recurrence.

It is interesting to note that the toxins used in this case, prepared by Dr. B. H. Buxton of the Lederle Laboratory, were eight months old.

Case VI. *Round-celled Sarcoma of the Dorsal Spine.*—Mr. G., aged twenty years. Diagnosis confirmed by Dr. Harlow Brooks, pathologist of the Bellevue Hospital. The tumor was of enormous size, involving the lower dorsal and upper lumbar vertebræ. The patient had lost about fifty pounds in weight, and there was so much pressure upon the spinal cord that there was total paralysis of the lower extremities, bladder, and rectum, and he was so weak that he was unable to turn over in bed. Seen in consultation with Dr. V. P. Gibney of the Montefiore Home, in February, 1902. The mixed toxins of erysipelas and bacillus prodigiosus were begun and continued by the house staff under my direction; daily injections were given up to the following May, and severe reactions, temperature of 103° to 104°, followed most of the injections. Patient began to show improvement, local as well as general, almost at once. By September he was able to get out on crutches. In November he was shown before the New York Surgical Society by Dr. John Rogers. At that time he had regained nearly his normal weight and got about very well with the aid of a cane. In February, 1903, one year after treatment, he was able to walk perfectly well without support of any kind, and his general health had become perfect. He was able to resume his former occupation.

This I believe to be the most remarkable result ever obtained from the use of the toxins. Fortunately, there can be no doubt as to the diagnosis, since the tumor was not only examined by well-known pathologists, but specimens of the tumor have been preserved. I have shown this patient before various medical societies the past two years. He remained in perfect health five years after treatment.

Case VII. *Round-celled Sarcoma of Femur Involving the Lower Two-thirds of Shaft.*—A. G., aged nineteen years. A swelling was first noticed in the lower portion of the femur in November, 1901. This gradually increased in size, being accompanied by loss of weight and deterioration of general health. Physical examination on February 5, 1902, showed a large tumor extending from the condyles of the left femur to the junction of the middle and upper thirds. There was a fusiform enlargement of the entire lower two-thirds of the femur. On the outer aspect of the thigh, about one and one-half inches above the joint, there was a soft, fluctuating area just covered by thin and reddened skin. There was slight impairment of the functions of the joint itself. An incision was made under ether into the fluctuating area, and two or three ounces of clear serum, similar to that which is found in cystic degeneration of sarcomatous tissue, were evacuated. A curette was passed into the cavity of the bone and typically sarcomatous tissue removed. Microscopic examination by Dr. E. K. Dunham and Dr. B. H. Buxton showed it to be a round-celled sarcoma. The patient absolutely refused amputation at the hip, which I strongly advised.

The *x*-ray treatment was tried entirely as an experiment, four exposures a week being given for a month, at the end of which time the circumference of the tumor had decreased one inch. The treatment was discontinued for two weeks, during which interval the tumor had again increased nearly an inch. The treatment was resumed, and at the end of another month the circumference of the thigh over the center of the tumor was one inch less than the original measurement. The treatment was continued the entire summer to December, 1902. At this time the measurement of the left leg was the

same as that of the right. There was still some thickening in the lower part of the femur. The old sinus, which had never healed after the exploratory incision, was enlarged under ether and carefully curetted. Examination of the tissues failed to show any trace of sarcoma. The patient had gained twenty pounds in weight, but towards the end of December, 1902, began to show signs of a metastatic tumor in the left pectoral region; this grew rapidly until it became about the size of a hand, when it was partially removed under ether anesthesia; it was found to be very soft and highly vascular. Shortly after this a large tumor, the size of a child's head, developed in the right iliac fossa, extending from the costal cartilages down to the pelvis; it could be easily felt in the lumbar region. The local treatments with the *x*-ray in the femur and pectoral regions were continued, and in addition the mixed toxins of erysipelas and bacillus prodigiosus were begun. After a few weeks the large tumor in the iliolumbar region began to soften and break down, and on becoming completely fluctuating was opened posteriorly. A very large amount of necrotic tumor tissue was evacuated and the sinus was drained for about a year. While the tumor in the leg had apparently disappeared, there remained a marked thickening of the bone, and the sinus leading to the broken-down area persisted. Examination of several curettings failed to show any longer evidence of sarcoma. At the present time, four years after beginning of treatment, aside from the sinus in the leg, the boy appears to be in perfect health. There is at present no evidence of sarcoma to be found.

Case VIII. *Periosteal Round-celled Sarcoma of the Femur; Mixed Toxins Used before Amputation with the Result of the Apparent Saving of the limb.*—H. K., male, aged 10 years. Admitted to Dr. Gibney's service at the Hospital for Ruptured and Crippled on November 12, 1906, with the history of sporadic and severe pain in the left femur since July, gradually increasing to such an extent that the child was often awakened at night and cried during the day. His general condition was much impaired. He was treated for rheumatism for a time; a fusiform swelling of the central portion of the left femur was noticed shortly prior to his admission to the hospital.

Examination on admission showed a fusiform swelling of the central two-thirds of the shaft of the left femur six and a half inches long, extending to within two and a half inches of either extremity of the bone. There was irregular temperature of 101° to 102° and some local heat. The tumor extended entirely around the femur and was apparently about one-quarter to one-half inch in thickness. I saw the case in consultation with Dr. Gibney, and we believed the condition to be periosteal sarcoma. The diagnosis was confirmed by an exploratory operation which I made the following week. A periosteal tumor was found with tissues typically like sarcoma, and the diagnosis of round-celled sarcoma was made by Dr. Jeffries, the Pathologist of the Hospital for Ruptured and Crippled, and also by Dr. James Ewing of Cornell. Under my advice Dr. Gibney agreed to place the boy under the toxin treatment before amputating the limb, which in this case would have been a hip-joint amputation. The pain subsided almost immediately and the tumor showed a decrease in size. On two different occasions the doses were diminished and given only once or twice a week, instead of every day, and on both occasions the tumor at once began to grow rapidly, each time subsiding under increased doses and more frequent injections. In March he received five *x*-ray treatments. He is now getting the mixed toxins only once a week and there has been no further tendency to increase; the tumor has apparently nearly, if not entirely disappeared, the slight thickening that still persists being probably new bone formation which may never be entirely absorbed. The leg measures almost exactly the same as the other. The patient received in all eighty-three treatments.

The case is not shown as a cure; but to have been able to check and cause to practically disappear a rapidly growing round-celled periosteal sarcoma of the femur with the toxins, without sacrificing the limb, and to show the boy nearly six months later, is certainly worthy of report. This case, together with the similar one of round-celled sarcoma of the femur, with extensive metastasis cured by the toxins and well five years, goes far toward proving the wisdom of using the toxins as a preliminary treatment in sarcoma of the long bones before sacrificing the limb.

Case IX. *Inoperable Sarcoma of the Ilium* (no microscopical examination).—M. G., male, aged 13 years, referred to me by Dr. La Ferté of Detroit, Mich., in August, 1906. Family history good. Personal history: Two years before had fallen downstairs, striking on the left side of the pelvis; in bed two weeks; slightly lame ever since. The patient fell again a year later, striking on the same side; was laid up in bed for three weeks. Not long after the second injury there was noticed some diffuse swelling in the upper portion of the left ilium, near the crest and outer surface. This continued to increase steadily in size, accompanied during the last six months with some loss of flesh.

Physical examination in August, 1906, showed a tumor involving almost the entire left ilium, extending below and partially surrounding the trochanter. The tumor was of somewhat variable consistence, being hard in some places and soft in others; there was some limitation of motion in the left leg, especially on flexion of the thigh; there had been a good deal of pain during the last year, coming on in paroxysms. The patient was admitted to the General Memorial Hospital and immediately placed upon the mixed toxins of erysipelas and bacillus prodigiosus. Most of the injections were made into the gluteal region, some few into the tumor itself. The treatment was continued with three intervals of rest until March, 1906, since which time he has had no further injections. The tumor has nearly disappeared, although there is still some bony thickening of the ilium, which has materially diminished since the treatment was discontinued. He has nearly recovered from his lameness and has more than regained his lost weight, and is apparently in perfect health at the present time. The last examination was made on May 25, 1907.

I have had one other recent case, a sarcoma of the lower jaw, which disappeared under two months' treatment with the mixed toxins. The patient is still well at the present time, but the case is too recent to be considered a cure.

Case X.* *Inoperable Round-celled Sarcoma of the Tonsil and Neck Successfully Treated with the Mixed Toxins.*—A. L., age 11 years, Hartford, Conn. The patient was referred to me by Dr. William R. Porter of Hartford on November 8, 1906. The patient had always been in good health, except that she had had frequent attacks of tonsillitis. A year ago she had a small swelling in one of the glands on the right side of the neck. The mother does not know whether it entirely subsided or not.

*Cases X, XI, and XII presented before the Hartford Medical Society, May 27, 1907.

Two months ago she noticed considerable enlargement in this region, which increased rather rapidly. When examined by Dr. Porter in the latter part of October he discovered a large tumor, apparently originating in the right tonsil and nearly blocking up the pharynx. She was examined by Dr. McKnight and a number of other physicians in Hartford, and all considered the tumor inoperable. The patient was referred to me by Dr. Porter on November 8, 1906. Physical examination at this time showed a growth the size of half a hen's egg, on the right side of the neck, involving the pharynx wall and tonsil, nearly blocking up the passage. On the opposite side of the neck, just below the angle of the jaw, there is a tumor about the size of a small hen's egg, fairly movable, smooth in outline, fairly firm in consistence, skin not adherent. Diagnosis: Round-celled sarcoma of tonsil and neck. The toxins were begun November 9, 1906, and continued with two or three intervals of rest, one to three weeks in duration, up to the middle of May, 1907, the patient receiving in all between eighty and ninety injections, nearly all of which were given in the pectoral region; a few were given into the tumor of the neck, but none into the tonsil. After two or three weeks' treatment there was a marked softening of both neck and tonsil tumor. Examination in consultation with Dr. W. L. Culbert; the latter removed a portion of the tumor of the tonsil, and it was found that the central portion of the same had become entirely necrotic, and several drams of broken-down tumor tissue were curetted out. I also removed some tissues from the tumor of the neck, which also proved softened and necrotic in the center. Both specimens were examined at the Loomis Laboratory by Drs. Tracy and Buxton, and both proved to be round-celled sarcoma.

This patient was rather susceptible to the toxins, and was rarely able to stand more than two or three minims without a severe chill, followed by a temperature of 103° to 105°. The highest temperature was 106°.

In two months the tumor of the tonsil and the neck had entirely disappeared. Shortly afterward a new swelling developed in the neck, about one inch higher up. This swelling persisted for a long time in spite of continued and severe treatment. She also developed a small glandular tumor on the other side of the neck beneath the sternomastoid muscle. In February, while taking the treatment, she had a severe attack of herpes, involving the right pectoral region and entire right arm. This was extremely painful, and she was unable to take the treatment for about three weeks. In the early part of May there still remained some swelling in both sides of the neck, rather deeply seated, underneath the sternomastoid muscle, and I decided to explore under ether. I found the swelling consisted entirely of broken-down necrotic material which had not found an easy exit. Some of the tissues from both sides were sent to Dr. Tracy of the Loomis Laboratory, and microscopical examination showed no evidence of sarcoma remaining. The wound quickly healed. The patient was shown before the Hartford Medical Society on May 27, apparently perfectly cured.

Case XI.* *Recurrent Inoperable Round-celled Sarcoma of the Neck. Successfully Treated with the Mixed Toxins of Erysipelas and Bacillus Prodigiosus; Patient Well Five Years* (treatment carried out by Dr. McKnight of Hartford).—A. P., age 2 years 10 months. Family history good. The child had a small spot three-quarter inch in size in the right supraclavicular region, which was at first supposed to be a nevus. This gradually disappeared, but there soon followed a swelling above the right clavicle, which was first noticed in January, 1902. This increased very rapidly in size, and was operated upon on January 27 by Dr. William R. McKnight at the Hartford Hospital, two weeks after its first appearance. It was then about the size of a hen's egg. No microscopical examination was made of the tissues removed at the first operation. Dr. McKnight states that it appeared to be a series of cysts. The wound did not heal and the growth apparently returned. A second operation was done a few weeks later. The specimen removed at this time was examined by Dr. W. R. Steiner, Pathologist to the Hartford Hospital, who made the diagnosis of small round-celled sarcoma. It was impossible to make a complete removal, as at this time the disease involved most of the glands on that side of the neck. The patient was referred to me by Dr. McKnight for my opinion as to the wisdom of trying the mixed toxins of erysipelas. I saw the patient on March 8, 1902. Physical examination at this time showed a series of tumors just above the right clavicle and extending up to the mastoid region, occupying almost the entire supraclavicular and cervical region. Clinically, the tumors had every appearance of a rapidly growing, round-celled sarcoma, which coincided with the pathological diagnosis made by Dr. Steiner. Dr. S.'s report was as follows: "The growth on the side of A. P.'s neck was operated on twice at the Hartford Hospital. I did not see the portion of tissue removed at the first operation. A portion of the tissue removed at the second operation was hardened and sectioned. I first saw it when it was cut and stained. From a specimen then seen I made the diagnosis of small round-celled sarcoma."

Although with such a rapidly growing tumor, primary in the glands of the neck, I considered the prognosis extremely bad. I advised a trial with the toxins. The toxin treatment was carried out under my direction by Dr. McKnight of Hartford, and the injections were continued for about six weeks. At the end of this time the tumors had softened considerably and become much smaller in size. After the treatment was left off they continued to disappear by absorption and the child entirely recovered her health. She is well at present, five and a quarter years since the treatment was begun.

Case XII. *Very Large, Inoperable, Spindle-celled Sarcoma of the Gluteal Region, Recurrent; Disappearance Gradual; Three Months' Treatment with the Mixed Toxins at the Post-Graduate Hospital, 1893; Well at Present, Nearly Fourteen Years after Treatment.*—M. S., female, 30 years. Original tumor removed by Dr. McBurney at the Roosevelt Hospital. Within two years the tumor had recurred and reached an enormous size, occupying the whole gluteal region, apparently attached to, but not involving the bone. Under the toxin treatment the tumor disappeared slowly by absorption, without breaking down or sloughing. Examination five years later showed two small masses remaining at the site of the former very large tumor. These I excised, and careful microscopical examination showed them to be made up entirely of fibrous tissue. The patient has been in perfect health ever since.

Lack of space prevents my reporting in detail the other successful cases. Those who desire further information in regard to them will find a complete report in the March issue of the *American Journal of the Medical Sciences*, 1906, comprising 36 personal cases and 60 successfully treated by other men.

* Not previously reported.

Since the publication of this paper, I have had six other successful cases, making a total of 42 cases. Of these 17 were round-celled sarcoma, 17 spindle-celled sarcoma, 2 mixed-celled sarcoma, 1 chondrosarcoma, 1 epithelioma.

In 4 no microscopical examination was made; yet the clinical features of the cases, such as recurrence after operation, rapidity of growth, size, and inoperability of the tumors, left hardly any doubt as to the diagnosis.

The late results in these cases are as follows: 21 well from 5 to 14 years, 26 well from 3 to 14 years, 10 well from 10 to 14 years.

The successful cases treated by other surgeons, brief histories of which I have given in the article referred to above (loc. cit.) show: 22 round-celled sarcoma, 14 spindle-celled sarcoma, 3 mixed-celled sarcoma, 3 endothelioma, 2 epithelioma, 16 in which no microscopical examination was made.

If the successful cases which have been reported to me since the publication of the paper mentioned were added, the number would, I believe, reach nearly one hundred.

THROUGH PHYSIOLOGY TO PATHOLOGY IN COMPLICATIONS OF GALL-BLADDER DISEASE.*

By G. K. DICKINSON, M.D.,

JERSEY CITY, N. J.

Until recent times pathology as written was terminal. As a sequence various conditions discovered from time to time in conjunction with disease states were considered as in part independent of the same, and given a specific term, "complication." Recent betterment of knowledge, obtained through experimentation on animals, through minor lesions existing without symptoms, discovered by the surgeon, and through advances in our knowledge of biochemistry, has demonstrated that these so-called complications are but an extension of the primary disease to other structures through channels of least resistance. Intensity of focal action and negative resistance on the part of the organism are the reasons for numerous lesions existent, but more or less quiescent in demonstration, while the original lesion, through its intensity, develops a train of symptoms masking all others.

Conditions leading up to an extension of disease processes of the region under discussion are (1) receptive nerve states; (2) obstruction of the flow of bile, on the one hand depriving the intestine of its accustomed fluid, and on the other the physiological and dynamic conditions induced by its failure to be discharged; (3) conditions of tension; (4) bacterial invasion, either ascending from the duodenum or transmitted through the blood; (5) inflammatory states in surrounding structures and their concomitants; (6) ulcerations through calculi; (7) hyperplasia of regular or irregular development.

1. When we consider that the gall-bladder region is supplied by filaments from the three divisions of the nervous system, the cerebral through the pneumogastric, the spinal, and the sympathetic, it is not to be wondered that a person in great pain should, through defect of nerve tone, have some disturbance in parts innervated by one or the other of these same nerves.

It is a matter of common observation that intense pain long continued produces a condition analogous to shock, viz., high tension, cold extremities, pallid and moist skin, etc. It is further observed that heart murmurs may develop at this time, persisting for one or more days after the pain has ceased. The plausible inference is that a paretic condition of the auriculoventricular ring has been induced, preventing a proper approximation of the valves. This, in degenerate hearts, may be sufficient to lead to death.

Reflexly through the sympathetic and pneumogastric, in interstitial pancreato-choledochitis, the parotid may be affected, characterized by excessive flow of saliva. Through the splanchnic, which has a continuity of neuron (differing from the spinal in that respect), we frequently obtain acute dilatation of the stomach or of portions of the intestinal tract, and may even find volvulus induced as a result of irregular intestinal peristalsis.

If appendicitis be preexistent without complete resolution, the lowered nerve tone may express itself there in pain and tenderness, substituting, as it were, the receding colic.

2. To state correctly the defects in digestion and intestinal tone due to the more or less complete suppression of bile flow, one should know the physiological value of the head of the pancreas as distinguished from the body and tail, as the former embryologically might be considered as an accessory to the liver, being an evagination from the common bile duct, whereas the latter is developed from a separated part of the duodenum. Later they seemingly become amalgamated, the ducts coalescing, nevertheless, by careful dissection the head may be cleaved from the body.

An important property of the bile, perhaps not fully appreciated, is its high surface tension. As oil thrown on water spreads out broadly, becoming iridescent on account of its tenuity, so bile entering the intestines drop by drop will disseminate over a large surface, invigorating the intestinal epithelia, so that, through their contained antienzymes protection ensues against both the acid stomach contents and the trypsin of the pancreatic juice, and also organic iron is more readily absorbed.

Defective elimination of bile, whether from obstruction or physiological causes, is often attended by a costive habit and a production of intestinal gases, probably due to absence of the cholates in the upper intestinal tract, Nature's physiological cholegogue.

If the bile be shut off from the intestinal tract largely or completely, we have, unless the hormones of appetite cut down fat-hunger, a putrefaction of fats coming on higher up in the intestinal tract, inviting the gas and colon bacilli to ascend higher than normal in their destructive work; the pepsin and hydrochloric acid from the stomach are not as promptly neutralized, and the pancreatic juice loses its physiological stimulus. As a result of these perversions we have increased tendency to epithelial degeneration, duodenal ulceration, diminished absorption of the products of digestion, and increased absorption of the products of putrefaction with their diverse effects and constipation.

If the obstruction be in the common duct and be persistent, bile will yet be secreted, only to be reabsorbed through the lymphatics, rendered patent by distention and rupture, leading to icteric conditions and cholate toxemia, with its depression of the central nervous system and terminal coma. This toxemia affects tissue cells of all types, injuring the capillary endothelia leading to spontaneous hemorrhages, the renal cells producing nephritis, the liver

*Read at the Annual Meeting of the Medical Society of the State of New Jersey, held in Long Branch, June 26, 1907.

and pancreas causing glycosuria, the blood retarding coagulation and inducing hemolysis.

If the obstruction be to the cystic duct, the bladder gradually enlarges from accumulation of secreted fluid containing large quantities of mucus. The coloring matter of the bile is first absorbed, and the bile salts next, the remaining fluid possessing none of its original characters.

If the obstruction be at the common orifice of the bile and pancreatic ducts, bile may pass into the substance of the pancreas and induce thereby the several types of pancreatitis—the interstitial and even the acute with hemorrhage.

3. Bile is secreted under low tension as compared with the product of some other glands. As a consequence, alteration in structure of the bile tract and liver induced through this condition will naturally be slow of progress. According as to whether the obstruction be steadily maintained or intermittent we shall have two distinct pathological results. Intermittent tension acts as an irritant, stimulating interstitial hyperplasia, which is followed by subsequent contraction. This gives interstitial choledochitis, the small contracted gall-bladder, and hypertrophic cirrhosis of the liver, occasionally associated with interstitial pancreatitis. On the other hand, when stasis is constant, the focus being on the gall-bladder, particularly when the obstruction is in the cystic duct, we obtain first, through compression, retardation of flow in the veins, then tissue degeneration, with or without preceding hyperplasia, terminating in the large and thick or fatty gall-bladders.

4. Through bacterial invasion, either ascending from the duodenum or migrating through the portal vein, local resistance being diminished, we have an extension and continuance of disease processes of a diverse inflammatory type. Bile not being bactericidal, and to a certain degree a culture medium, will harbor germs for an indefinite time. The gall-bladder without macroscopic evidences may be infested with *B. coli* or *B. typhosi* for many years, making the party an unconscious disseminator of typhoid fever. Suppurative cholangitis induces the intermittent fevers characterized by regularity of chills, and may produce multiple pyogenic foci in the liver. In the gall-bladder, particularly with impacted stones and tension, we may obtain acute cholecystitis and phlegmonous conditions leading to local or generalized gangrene.

5. By extension of inflammation surrounding structures become implicated—protective adhesions form with the omentum, which, if the inflammation be not too intense, may bring about resolution through the enzymes of the leucocytes and phagocytic action.

If adhesions attach the gall-bladder to the stomach, near the pyloric end or the duodenum, changes in position of the liver may produce traction on the same, inducing gastric dilatation, or evidences of irritation in the neighborhood of the adhesion. Massive adhesions to the transverse colon may inhibit its action, producing a similitude of cancerous invasion. A heavy pendant gall-bladder can in time drag downward the liver margin, so that thereby adhesions occur between it and the appendix, and even the pelvic organs.

If the gall-bladder be in any of its anomalous positions posteriorly or in the substance of the liver, conditions similating abscess formation in those parts may follow.

6. The pressure of calculi in inflamed or degenerate gall-bladders or ducts will, through pressure necrosis, cause ulceration; if adhesions form, calculi may pass through them to adjoining viscera, such as the stomach, intestinal tract, or urinary bladder; and if no adhesions occur peritonitis ensues. If a stone should slough out of the ampulla of Vater its sphincter muscle will be obliterated, and microorganisms and acid gastric juices before being neutralized by the alkaline juices of the duodenum will gain entrance to the pancreatic duct, particularly if Ochsner's ring be spastic, and set up some type of pancreatic disease.

7. Calculi often become impacted in the cystic duct, and after a process of time produce hyperplasia of the mucosa, which may take on adenomatous changes and eventually become a true adenocarcinoma, spreading by dissemination peripherally.

280 Montgomery Street.

REINFECTION WITH SYPHILIS;

REPORT OF A CASE WITH HEREDITARY SYPHILIS IN THE CHILD.*

By JAMES BREW, M.D.,

NASHVILLE, TENN.

On August 15, 1905, Mr. G. S., white, male, age 37 years, occupation saloonkeeper, consulted me at my office for a sore upon his penis. The chancre, which was situated in the fossa glandis, was first noticed July 14. The patient was of good physique, with no scars or blemishes on his body, except a scar on the glans penis, which he claims followed a *coitus ab oro*, and an abdominal scar as result of celiotomy. There were no deformities.

The father was dead, the mother was living and in good health. She was subsequently treated by me for passive congestion of the brain. She made a good recovery from this, and when last seen was in good health. Two brothers and one sister were living and in good health. The man was married to a widow five years ago, she having a living child by a previous marriage. There were no children from this marriage. The wife enjoyed excellent health up to about two months before her death, when she was operated upon for sarcoma of the cervix uteri, attributed to a lacerated cervix occurring at her confinement, and which had received no treatment afterwards; her age at death was twenty-eight years.

The patient's occupation necessitates irregular hours; he takes only such exercise as his business demands, which is chiefly walking to and from his business. The appetite is usually good, but he eats irregularly and often immoderately; uses tobacco and alcohol. His sexual life is in accord with his other excesses, and he cohabits promiscuously and at frequent intervals.

During childhood he had measles and whooping-cough; no other diseases of childhood. About one year ago he had an acute attack of appendicitis, made a good recovery from first attack, but had several recurrences during the year, and was finally operated upon; from this he made an uneventful recovery.

At the age of 17 years (or twenty years ago) he was treated by his family physician at his home in Louisville, Ky., for a venereal ulcer, the nature of which was at first in doubt. He describes this ulcer as appearing on the foreskin, and looking at first like a fever blister; it did not extend very rapidly, but soon became very hard; he had no bubo, and

*Read before Middle Tennessee Medical Society, Murfreesboro, Tenn., May 17, 1907.

does not remember having had very much discharge, but the ulcer was very slow to heal. He continued under the care of this physician for four or five weeks, when he consulted another physician, the latter a venereal specialist. At this time an eruption had made its appearance and a diagnosis made was of syphilis in its second stage. He was given syphilitic treatment for three years, and took medicine as prescribed every spring and autumn for two years afterwards. Since the eruption disappeared he has never had any syphilitic manifestations, except six years afterwards (or nearly fourteen years ago), when he had syphilitic rheumatism, which responded to mercury and iodides. Since that time he has never had even a reminder. I have treated the patient personally for specific urethritis, stricture, and chancroid. He has had herpes several times; for this he never consulted a physician, he himself being able to effect a cure.

On July 14, 1905, the day before he went to the hospital for an operation for appendicitis, he called the attention of his medical attendant to a sore which had appeared on his penis. After an examination he was told that it was inconsequential; it was touched with a solution of silver nitrate and a cotton pledget was applied as a dressing. During his stay at the hospital the ulceration remained, but gave very little trouble; he dressed it several times, applied some form of dusting powder furnished by the hospital attendant, but did not call the attention of his medical attendant, as he did not consider it a matter of any gravity.

On August 15, after his dismissal from the hospital, I saw him for the first time for his present trouble. Upon examination I found an inflamed, nonadherent, densely indurated mass about the size and shape of a half peanut; there was no ulceration or excoriation, but it was of a dark-red color and congested appearance, not tender to the touch, but slightly so under pressure; very slight discharge. The inguinal glands on both sides were palpable, each gland separate and distinct; the post-cervical and epitrochlear glands were also palpable and slightly tender.

He stated that three weeks before going to the hospital he had intercourse with a prostitute; he was positive that he had had no other intercourse during the interval, for a few days afterward he suffered from the attack of appendicitis, for which he had to be operated upon. This sore first appeared as a papule; there was no pain, no tendency to spread, and no discharge. I have described as clearly as possible the course it pursued until I first saw it. The chancre was treated locally by washing daily with 1-5,000 bichloride of mercury solution, calomel powder, and bichloride gauze. No internal treatment was given whatever. Under this treatment the inflammation subsided, but the induration continued, and was present to a degree for several months afterwards.

On August 25, at his daily visit to my office, he complained of a severe headache, frontal, and a general aching throughout the body. He had suffered so much the night before that he was unable to sleep. Still not wanting to give anything internally which would influence his condition one way or the other, I directed that he take a Turkish bath that evening and remain at the bathhouse overnight and report to me the next morning. This he did; was still complaining of the headache, feeling very badly in general, had eaten nothing since the day before, and complained in addition of a very sore throat.

Upon examination I found his chest and abdomen pretty well covered with an eruption. This consisted of rose-colored blotches, not elevated above the level of the skin. In a few days it became darker in color, and finally copper-colored. The eruption extended to the upper part of the thighs and onto the buttocks. It was diagnosed as erythema maculatum. Throat examination showed a general diffuse redness, no points of ulceration; some discomfort and difficulty on swallowing.

Mercurial ointment inunctions were made nightly, changing the site of application each treatment. Pills containing one-half grain protoiodide of mercury were ordered, one pill to be taken three times a day, the dose increasing by one pill every other day until symptoms of mercurialism began to manifest themselves. Precautions were enforced as to eating; all alcoholic drinks were interdicted; smoking was permitted in moderation, and the patient was ordered to refrain from sexual intercourse and avoid sexual excitement.

Two days after beginning treating my patient was called to Louisville, Ky., on business. While there the mercury began to show its effect, causing a diarrhea; he called me up on the telephone to report his condition. I advised him to see his former medical adviser and to have him make a thorough examination of him; this he did.

The induration following the chancre was still present, as was also the glandular involvement, the eruption sufficiently distinct to be recognizable. The diagnosis of syphilis was confirmed, and the physician remarked that "if he did not know that he had had syphilis before, he would say that it was a new attack." The question was then asked if there could have been any doubt as to his having had syphilis when he had waited upon him fifteen years ago, but he was assured that it was syphilis then and that it was syphilis now.

In April, 1906, the patient was again married, but it is hardly necessary for me to say that he entered this state without my consent or advice. He was warned in advance that any children would in all probability be syphilitic. This forecast proved only too true. From the time of his last infection up to the time of his marriage he remained under my care and treatment, and with the exception of two or three instances, when he drank to excess, was a very good patient.

In March, 1907, his wife gave birth to a girl baby, well developed, weighing eight and one-half pounds, and to all appearances a normal child. During the past month, the child's seventh week of life, I was called to see her for what the mother supposed was a cold. Temperature and pulse were normal, appetite good, the baby nursing at regular intervals and digesting food. The bowels were slightly constipated, but otherwise normal. The child slept well. The chief symptom of concern was a coryza and snuffling, worse at night. I prescribed calomel and soda, to be followed with castor oil to cleanse the alimentary tract; in addition I gave Dover's powders in suitable doses, and an inhalation of compound tincture benzoin and paregoric. After three days of this treatment it was very apparent that the baby was not improving, the snuffles, if anything, being worse. Convinced that it was a case of syphilitic inheritance, I then prescribed half a grain of calomel, bicarbonate of sodium twice daily, and inunctions of mercurial ointment. For the nose I prescribed nitrate of mercury ointment, to be heated and applied locally. After the first few days the child began to improve, and at the present writing the snuffles have disappeared and the child is in fairly good shape. No eruption has appeared. The

treatment will be continued along the same lines as here outlined.

All authorities recognize three immunities against syphilis: (1) In a person who has suffered from the acquired form of the disease; (2) in a person who has inherited the disease from one or both parents (Profeta's law); (3) in a woman who has borne a syphilitic child without showing in her own person any of the lesions of acquired syphilis (Colles's law).

There are several sources of fallacy in diagnosing a second attack of syphilis that must be remembered: (1) A nonspecific general eruption may accompany a chancroid. (2) Impetigo contagiosa, ecthyma, or some form of eczema may be mistaken for true syphilis, and, if it follows a genuine attack, be cited as a case of second infection, or the first attack may have been impetigo or eczema and the second true syphilis. (3) A chancroid or mucous patch may become the seat of such marked inflammatory induration that it is mistaken for the true chancre. (4) A tertiary gummatous ulcer may be mistaken for a hard chancre. (5) There may possibly be such a thing as recurrent chancre. (6) Not infrequently chancre almost entirely disappears, yet a slight induration remains, which at some subsequent period enlarges into a similitude of a new initial sore (Lydston[1]).

White and Martin say:[2] "Although, as already stated, syphilitic reinfection is exceedingly rare, it unquestionably occurs in some few cases. In the great majority of cases reported, the symptoms could be more satisfactorily explained by regarding them as recrudescences of the original attack. Fournier states that reinfection is certain only when the following conditions can be noted in their proper chronological order: An indurated chancre with indolent inguinal pleiades; some weeks later, a typical roscola or other syphilitic eruption, cephalalgia, alopecia, or mucous patches; a complete absence of tertiary accidents for some years; finally a new indurated chancre after a suspicious intercourse with characteristic adenopathies, followed, after some weeks, by incontestable secondary manifestations, such as headache, alopecia, mucous patches, typical eruptions of the macular or papular syphiloderma, or other syphilides."

Taylor says:[3] "As a general rule, syphilis, like smallpox, scarlet fever, measles, etc., etc., attacks the individual but once in a lifetime, but a sufficient number of well attested cases have been published to warrant the statement that in certain rare instances syphilis does attack the individual twice in his lifetime. There have been published up to date about one hundred and sixty cases of syphilitic reinfection, and it is safe to say, allowing much latitude, that not thirty of the whole number are authentic instances. When we carefully review the whole subject we may admit that genuine second attacks of syphilis occur, but they are very rare. all unsuspected and putative cases should be approached with caution and reserve rather than with a sanguine and credulous spirit. Before a given case shall be accepted as true, and beyond controversy, the following facts must be established as clearly as possible: In the first attack, the existence of a true hard chancre, followed by characteristic adenopathies, and a clear history of the secondary stage and its lesions, and perhaps a tertiary stage. Then a sufficient long period of time should elapse in order to show that the diathesis has become extinct. Many cases have been reported in which only one, two, or three years only have elapsed between the two so-called separate attacks of syphilis. Such cases are, without doubt, apocryphal. In the light of the cases already published, it is not too much to say that no case is worthy of consideration in which the interval between the cure, or apparent cessation, of the first attack and the onset of the second one is at least not under five or six years. The future requirements are that the history and characteristics of the second chancre shall be satisfactorily made clear, and the involvement of the ganglia established beyond a doubt. Then the clear clinical picture of the period of general manifestations must be given before we accept the case as one of second infection with syphilis. If these requirements are fulfilled it is safe to say that in the future we shall not be favored, as we have been of late, about once in two or three months, with a new case of syphilitic reinfection."

Keyes says:[4] "Syphilis once acquired stamps its impress upon the individuality of the patient and becomes a part of him, and no power on earth, in a given case, can say when the impress disappears. A half century may pass away and the trail of the serpent is still visible. This is a fact, and as such must be recognized. It is of vast importance, and to shut our eyes to it would be folly. That we do not shut our eyes, even those of us who believe in an early and radical cure of syphilis, is sufficiently shown by the avidity with which in doubtful cases of skin and bone disease the history of the patient is carefully inquired into for a record of a pre-existing syphilis, which, if found, no matter how far distant, makes a diagnosis, establishes the treatment, and often leads to a cure. Yet in spite of this assertion, who shall say that syphilis is not curable? Occasionally cases are seen where syphilitic chancre is acquired a second time, followed by crops of secondary eruptions, and surely in these cases the old syphilis must have been cured, or the new case could not have occurred. The possibility of the duration of the effects of syphilis must be recognized by every intelligent physician who wishes to accept facts and desires to view syphilis in a practical light. The probability of the disease in most cases, however, is that its manifestations will disappear finally after a few years, and this under the intelligent management becomes almost a certainty."

Taylor again says:[5] "Syphilis in healthy persons, male and female, as a rule, runs a mild course, and its poisons eliminated from the system if active treatment is instituted at the proper time. Much depends on the docility and intelligence of the patient, who, if he enjoys ordinary good health and will follow up energetic but very carefully directed treatment, may, I am confident, be cured. Thirty years' study and observation of the nature and treatment of syphilis has convinced me that in most cases a cure is possible, whereas, in years gone by, we groped in ignorance, pursued faulty, even harmful, methods, and never felt ourselves masters of this insidious and far-reaching disease."

Lydston,[1] in reviewing cases of reinfection with syphilis, says: "Such cases are especially interesting, both from their rarity and from the fact that they must conclusively prove the curability of syphilis."

Marshall[6] says the following: "The curability of syphilis would appear to be proven by the occurrence of reinfection, and it is probable that most attacks are cured. A recent publication of Tarnowski[7] is of great interest in connection with this subject. He has collected fifty cases which he has followed up to forty years. The conclusions he arrives at are as follows: (1) Syphilis is curable at all periods of its evolution. The disease may be limited to the initial lesion, but cure generally takes place in the

second stage. A complete cure may happen in the tertiary stage. (2) Medication by mercury and potassium iodide was employed in the cases under consideration, but this treatment was not the only factor employed in the cure of syphilis. (3) A robust constitution, absence of hereditary predisposition, and freedom from other diseases are important factors. (4) The curability of syphilis is influenced by the resistance opposed by the organism —an inherent resistance peculiar to each individual which cannot be well defined. (5) The danger of syphilis depends on the localization of the symptoms and the phenomena known as parasyphilis."

"The analysis of Tarnowski's fifty cases gives the following: The disease ceased on the average twenty-eight years after the infection. Patients treated during the first four years with mercury and iodide of potassium remained free from any symptoms for twenty years. In one case only the disease was limited to the initial lesion. In thirty-one cases out of the fifty there were no tertiary symptoms; the rest were cured after having suffered from gummata. Of the forty-eight men who had had syphilis, twenty-seven married. Two women also married after infection. Of these twenty-nine marriages, six were sterile, twenty-three gave birth to sixty-three children, of which fifty-six presented no signs of hereditary syphilis. All of the patients with one exception belonged to the educated classes. Treatment was prolonged and most of the patients were given iodide of potassium for several years after a cure with mercury. Few of us are able to trace the history of our syphilitic patients for many years. Tarnowski covers more ground than most specialists and the cases reported by him are, therefore, of much importance."

Tarnowski's opinion regarding the curability of syphilis, the length of time necessary to effect a cure, and the results obtained in the fifty cases under his observation and reported by him, are, to say the least, very unsatisfactory from a cure standpoint, inconsistent, and not in accordance with the results obtained by the syphilographers of this time and age and with whom we are now familiar.

In the case which I report, the patient was treated twenty years ago for a venereal ulcer, followed in about five weeks with an eruption; he had mucous patches, and later a rheumatism which responded to treatment by mercury and the iodides. For fifteen years he had never had any symptoms of syphilis, not even the "reminders." At the time of his first infection he was treated at first by his family physician; upon the appearance of the eruption he was seen by a venereal specialist, a gentleman of recognized ability, and his condition was diagnosed as syphilis. He was put on mercury and iodide of potassium and the treatment was continued for three years. For two years afterwards he was under the care of this same physician and took such remedies as were prescribed for the period mentioned. Five years ago the patient married, and while there were no children as a result of this marriage, there is still an absence of any history of abortions or miscarriages.

Before his marriage, and after the death of his first wife, the patient had contracted other venereal diseases, he had led a life of excesses, both sexual and alcoholic, but there never was any suspicion of his original syphilis during this interval of fifteen years.

Four weeks previous to the appearance of his last chancre he had an intercourse with a prostitute, followed by a sore upon the penis. The character of that sore I have described. Just four weeks after the appearance of this sore he complained of frontal headache, worse at night, general aching throughout the body, sore throat, and the next day an eruption made its appearance after he had taken a Turkish bath. The character of this eruption I have also described. While the eruption, the induration following the chancre, and the glandular involvement were still present he consulted the physician who had treated him for his first infection. This physician confirmed the diagnosis of syphilis and further stated that he was just as sure that the attack twenty years ago was syphilis as he was of his present trouble being syphilis. After several months' treatment he married again, the child born of this union is most positively syphilitic and is now under my treatment for the disease. The mother has never shown any symptoms of syphilis.

This is most certainly not a case of tertiary manifestation, for it does not present any of the features that would justify my so calling it. The case, I think, meets all the requirements as laid down by Fournier, Taylor, White and Martin, and others, to justify my claiming it as a case of reinfection with syphilis.

THE LONG-WAISTED WOMAN AND HER MOVABLE KIDNEY.*

By A. ERNEST GALLANT, M.D.,

NEW YORK.

In 1902, the writer after carefully studying several hundred cases of splanchnoptosia, in a clinical lecture before the New York School of Clinical Medicine,[1] gave expression to the "developmental theory" of that disorder in the following terms: "At puberty, when the girl is rapidly increasing in stature, and her menses begin to drain the system, relentless custom adds to the enormous strain by interdicting skipping, running, and jumping. Healthful exercise may no longer be indulged in; she must be compressed within a corset; her clothing no longer suspended from the shoulders, but hung from the waist by tightly drawn bands, and the light, short skirts are exchanged for long, heavy, trailing dresses; yet we wonder that the health of the young girl breaks down when thus hampered, haltered, and harnessed. Ere long the plump, rosy-cheeked, vivacious girl becomes the sedate miss—anemic, dyspeptic, constipated, nervous, restless, sleepless; and her parents wonder why, fearing that the heretofore lovely girl is about to be carried off by consumption."

This change we believe to be brought about in the following way: "As the spinal column at this age rapidly lengthens it should carry upward all the viscera attached thereto, but owing to the weight of clothing and compression at the waist-

*Read by invitation at the annual meeting of the Suffolk County Medical Society, held April 25, 1907, at Patchogue, L. I.

line this process cannot take place: stretching of the ligaments occur, the viscera are prevented from rising, and hang at a level much below normal."

Whenever a patient in this class applies for relief we notice that she is slender, with undersized hips, her clothing fails to hide the almost masculine figure, and lacking the graceful curves of a well nourished woman.

When rehearsing her history, she does so in a sing-song fashion, with the glibness of an oft-repeated tale; involving disorder of the stomach and intestines, irregular pains, headache, lassitude, loss of flesh and strength, inability to attend to her duties or pleasures, and, most characteristic of all, inability to tighten her clothing and corsets or to wear any corsets at all.

For the purposes of this paper we have reviewed fifty cases, and careful measurements of these patients constantly show definite abnormality in one or more of the following respects: (1) The length of the trunk, as shown by the distance between the suprasternal notch and the upper border of the symphysis pubic, varies from 19 to 23 inches, regardless of the individual height, which ranges from 5 feet 1 inch to 5 feet 11 inches, approximately 26 per cent. of the subjects measuring 19 and 20 inches, and 23 per cent. 21 and 22 inches. But one girl 5 feet 3 inches in height measured 18½ inches, and another 4 feet 10 inches measured 18 inches between the same points, and a weight of only 90 pounds. (2) A deviation from the normal relation between the circumference of the waist and the hips over the great trochanters, of from 2 to 12 inches, and averaging a loss of flesh of 5 pounds to the inch, or from 10 to 60 pounds underweight. These factors are so constantly present that those who come in contact with large numbers of this class of patients learn to recognize them at a glance, and make the diagnosis at sight.

Inspection of the abdominal wall shows a characteristic configuration. A hollowing of the epigastrium (Fig. 2x), and a bulging of the hypo-

gastrium (Fig. 2z), the whole resembling an inverted interrogation mark. In thin walled individuals, a respiratory rise and fall of the greater curvature of the stomach can be distinctly seen.

In order to determine the real relation of the viscera, and show the excessive distortion when the woman has her garments on, it is our custom, when examining, to tie a piece of bandage around the waist just as tightly as the woman makes her waistbands, with the result shown in figure 3.

Careful measurement with a lead tape, from one anterior superior spine to the other shows (Fig. 4) the—

all associated with more or less gastric dilatation.

The four cases with the greater curvature of the stomach *above* the umbilicus were considered in normal position, and the remaining 38, or about 90 per cent., as displaced. The 12 cases in which the lesser curvature was palpable (30 per cent.) were designated prolapsed stomach, as compared with the other 26 cases (60 per cent.) showing some degree of dilatation of the stomach.

Succussion, or the splashing sound, was more or less well marked in 7 cases, and was not difficult to elicit when there was fluid in the stomach, sometimes when the patient was lying down, in others when standing.

The appendix had been removed in 2 instances; was palpable in 12 cases, of which 1 was normal, 3 tender to touch, 1 behind the caput coli, 2 had had recurrent attacks, and in 13 that organ could not be defined.

Cancer of the pylorus was made out in one case, referred to Roosevelt Hospital; the pylorus was removed by the surgeon in charge, and the patient died a few days later.

The left kidney was prolapsed in but *one case*, the right kidney in 34 instances, the *lower pole being below the chondral border.*

Inches	½	1	1½	2	2½	3	3½	4	4½	5	6	7	8
Cases	1	2	2	4	5	10	2	4	1	2	2	1	1

In nine patients neither kidney was palpable, and no record in five. In one case the right kidney had been removed some years before, showing a total of 80 per cent. in which the kidney was involved. The kidney was replaceable by posture and manipulation in thirty-one instances, partially so in one, and adherent in three.

Transillumination of the stomach was practised but three times in this series of cases, as it can do little more than confirm what the practised eye, ear, and hand had already determined.

The history of splanchnoptosis usually dates from puberty, occasionally follows trauma, is very common in parous women, and in those who have had large abdominal tumors removed. The rapid loss of a large amount of flesh during severe illness is often followed by prolapse of one or more of the abdominal viscera. The various phases are best shown by the following illustrative cases.

Case I.—Dislocated right kidney in a child, simulating appendicitis. H. G., Jr., aged 10 years, granddaughter of Dr. J. J. B., Exeter, N. H., seen in consultation December 3, 1905. Four days be-

fore, illness began with vomiting and pain located in the right iliac fossa, without distention, or abdominal rigidity. Temperature had ranged from 97.8° to 98.4° F., pulse 100 to 120. Calomel was given for constipation, and she vomited everything taken by mouth, stools very small. Examination shows abdominal wall lax, intestines empty, stomach contracted; some soreness in the epigastrium, and tenderness on the inner side of McBurney point. Right kidney prolapsed two-thirds of its length; tender on pressure, easily replaceable. Treatment: The child was placed flat on her back, the foot of the bed elevated eight inches, and a snugly fitting abdominal binder applied. Measurements were taken for a special corset, which was put on two weeks later. She has worn this same style of corset ever since, and has not suffered since the kidney was replaced on the day of examination.

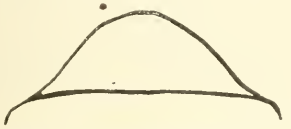

FIG. 4.—Abdominal projection; lead-tape outline between anterior superior spines; curved line, when standing; flat line when lying on back.

Nephroptosis of traumatic origin occurred twice in this series: CASE II.—Dislocation of the right kidney with hematuria, from a fall. Mrs. H. F. M., wife of a Toronto physician, who, recognizing the source of the lumbar pain, placed her in bed, and wrote for one of my corsets, which was put on December 27, 1903. April 5, 1905, the doctor wrote me, "My wife's corset, after the stiffness wore off, has been quite comfortable. A few weeks ago she got a second one. The range of mobility of the kidney in the anterior axillary line cannot be more than an inch and a half or two inches at the most, and is more painful. A false step occasionally causes a dull ache in the loin, which usually passes off in a few moments, especially if she is able to lie down." This pain was due to the fact that the corset was not laced tightly enough at the waist to immobilize the kidney and was easily remedied.

CASE III.—Miss L. M. R., sent to me by Dr. C. E. Shaw, of Hoosick Falls, N. Y. On October 18, 1906, she said that about a year ago, after tobogganing, there was swelling and pain in the right loin, which passed away in a few hours, but there has been more or less of the same discomfort ever since. Examination shows a well formed woman, of 23 years, 5 feet 8 inches in height, weighing 138½ pounds; waist measuring 26 inches, hips 39 inches (good proportions), suprasternal notch to symphysis, 20½ inches. The right kidney descends 2 inches, is replaceable; the greater curvature of the stomach lies just above the umbilicus. Abdominal projection 1½ inches. November 26, 1906, she complained that, while the corset gave relief, it would slip up when she sat down. Lacing more tightly at the waist overcame this difficulty, and she was relieved of all her symptoms, except an overanxious mother.

The stretching of the abdominal wall during pregnancy and the rapid emptying of the uterus during labor leaves the abdominal wall very lax, the ideal condition for the production of visceral ptoses, which will certainly follow if we fail to apply a snug abdominal binder, with exercises while the patient is in bed, and provide for abdominal support when the patient gets about.[2] I have already reported several cases of acute jaundice during the puerperium caused by traction of a prolapsed kidney on the common bile duct, promptly relieved by elevating the foot of the bed, and cured by a properly fitting corset.[3]

Hydronephrosis, due to kinking of the ureter, is the most common result of kidney prolapse, manifested by the syndrome known as Dietl's crises—sudden attacks of nausea, vomiting, pain, tenderness, and swelling along the right loin, sometimes to enormous proportions; which quickly subside when the patient is placed in bed with the foot raised 8 or 10 inches.

SYMPTOMATOLOGY: KIDNEY VS. THE GASTROINTESTINAL TRACT

	Kidney Group	Gastrointestinal Group
Onset	Acute attacks, intermittent from day to day, Dietl's crises more or less constant.	Chronic
Pain	Abdominal, hypochondriac, through to back, down loin, very intense in a few hours.	Epigastric, cardiac, to left shoulder and arm, after eating.
Abdomen	Distended on same side.	Bloating
Stomach	Nausea, vomiting, even when empty.	Regurgitation of gas, water-brash.
Bowels	Constipation-diarrhea, stools dark or clay color.	Seldom move without drugs, catarrhal colitis.
Urine	Scanty, dark, acid, with or without pus or albumin.	Usually frequent, small quantity, often dysuria.
Pulse	Small, rapid, high tension.	Small, rapid, low tension.
Corset and clothing	Must be loosened at once	Must be worn loosely all the time.
Associated with	Hydronephrosis, jaundice, or hematuria.	Autointoxication, malnutrition, loss of flesh and strength, headache, sleeplessness, nervousness, physical and mental malaise, uncertain temper, etc.
Response to treatment.	Early relief when placed in the inclined dorsal posture. Return of attack when resumes the upright posture.	All the usual remedies, bandages, and belts fail to afford permanent relief.

Referring to the table on symptomatology we note the striking difference between the clinical manifestations arising from the movable kidney which bobs up and down with every change of posture, and the doleful picture of the "hell on earth" experienced by those who suffer from gastrointestinal displacement, distortion, and disease, without any permanent relief from the ordinary methods of treatment—medicinal, mechanical, or surgical. This condition was present in varying degrees in all but three of the fifty cases, and was demonstrated to be due to dilatation of the stomach, prolapse of the stomach, or both, associated with dislocation of the colon, especially in its transverse portion; with consequent retention of food and feces, and autointoxication.

In 1893, the writer began using ready-made corset for the immobilization of mobile kidneys, and on April 18, 1901, before the College of Physicians, Philadelphia, gave the first description of the style and mode of application of a custom-made corset for this purpose.[4]

The new features brought into play by the writer's method involves (1) the replacement of the prolapsed viscera in the semiopisthotonos posture (Fig. 5); and (2) suprapubic support of the replaced organs by the wearing of a specially constructed corset,[5] made from measurements, taken by the physician, while the patient is lying on her back. Briefly, this garment is a simple modification of an ordinary corset, which reaches low down over the hips, and to the symphysis in front, of fashionable design, gracefully curving in at the waist and out over the hips (padded inside for

women with small hips). The front section is made V-shaped, narrow at the symphysis, broadening out toward the top, to provide ample room in the epigastrium for the replaced stomach.

When about to put the corset on, the patient loosens the lower lace (laced from the waistline down), the upper one being of thin hat elastic, wraps the corset around her waist, lies down upon her bed or a couch, raises her hips as in figure 5, rubs and strokes the stomach upwards toward the

Fig. 5.—Semiopisthotonos posture; hips raised, causing the viscera to gravitate toward the diaphragm, when fastening the corset, for the support of the organs replaced.

diaphragm, fastens the hooks from the lowest one up, and draws in the lower lace as tightly as possible, without lowering the hips until the lacing has been accomplished. No belts or buckles, straps, or airpads, except the ordinary garters, are required, and are only found on garments made by those who fail to grasp and apply the principles involved.

Before recommending a corset for splanchnoptosis it is necessary to determine: (*a*) Is the kidney replaceable, or safely fixed in the false pelvis, where it cannot be injured or compressed by the waistband? (*b*) Does the lower border of the stomach rise to or above the umbilicus when the patient is in the semiopisthotonos posture? The importance of this question was shown in Case 4, where it was necessary to open the abdomen and release the stomach from its attachment to the sigmoid flexure of the colon, caused by appendical peritonitis. Immediately after the adhesions were loosened the patient vomited, the stomach contracted, and with the wearing of a corset it never sank lower than the umbilicus. This class of cases is fairly frequent, and demands operation before adjusting the corset.

Case V.—This is an example of an unfortunately frequent and disagreeable result which has followed the epidemic of surgical enthusiasm for kidney fixation. The woman wore a ready-made corset with partial relief from October, 1901, to 1904. Her right kidney was then sutured by Dr. Goelet, August 20, 1904. The kidney had dropped three and one-half inches, November 25, 1904, and I fitted her with a corset. When last seen, April 9, 1905, she had been much relieved, was able to take long walks, but experienced soreness at the umbilicus, due to want of room in the upper part of the corset.

Three cases required the removal of fibroids, one of the appendix, one ectopic pregnancy, one ovarian hematoma before putting on the corset; while, on the other hand, the corset gave relief, most extraordinary, from suffering following ventrofixation; also in postoperative ventral hernia of large size, and resulted in saving both women from the necessity of secondary operations.

Prof. J. C. Da Costa, writing on "A Modified Operation for Movable Kidney,"[6] says: "In many cases of movable kidney, I believe that it is unwise to operate at all, the use of a properly applied corset being relied on to keep the patient comfortable and safe. The corset devised by Dr. Gallant accomplishes this purpose more successfully than any one of the so-called kidney supports." This substantiates my original claim that 95 per cent. of movable kidneys can be handled better without operation.

Results.—From the fact that thirty-two of these patients were sent to me by twenty-seven physicians, residing in nearly as many States and countries of North America, it is imposible to tabulate the actual results of this plan of treatment; but it can be honestly stated, and without exaggeration, that whenever a corset has been properly fitted and put on after this plan the woman at once realizes a sense of comfort and support to which she has heretofore been a stranger, with cessation of the so-called attacks. As time goes by her friends notice a well marked improvement in her general health, in temperament, in appearance, in weight, in ability to walk, work, sleep, eat, and enjoy the good things of life.

To me, personally, the most flattering evidence of the usefulness of this method of treating Glenard's disease has been the numerous attempts at improving the style of corset, by encumbering it with all sorts of "contraptions"; and its adoption by the editors of a well-known Genitourinary Surgery, who forgot to make mention of the paternity of the child. "Imitation is the sincerest flattery"—*Colton.*

APOMORPHINE IN ACUTE ALCOHOLISM;

A PLEA FOR ITS MORE EXTENSIVE EMPLOYMENT.*

By CHARLES A. ROSENWASSER, M.D.,

NEWARK, N. J.

INEBRIETIST TO THE NEWARK CITY DISPENSARY; ATTENDING PHYSICIAN TO THE NEWARK POLYCLINIC.

The acutely intoxicated individual, besides being a menace to himself, is usually such a great source of annoyance and distress to those about him, and is ordinarily so difficult to subdue, that any remedy which will promptly convert the state of pandemonium into one of calm, and effect a decided change for the better, is certainly deserving of recognition and ought to be extensively employed. Especially so if the remedy is an absolutely safe one and can be administered without the consent of the patient, for you all know how obstinate he is apt to be, and how great a task it often is to induce him to swallow medicine. In apomorphine we possess such a remedy.

Apomorphine is an artificial alkaloid prepared from morphine, usually by heating morphine in a

*Read at a meeting of the American Society for the Study of Alcohol and Drug Neurosis, June 6, 1907.

closed tube with an excess of hydrochloric acid. It was first discovered by accident by Matthiessen and Wright in 1869 as a by-product in the manufacture of morphine. Apomorphine hydrochlorate, the form almost exclusively used, results from the addition of a small quantity of hydrochloric acid to apomorphine in solution.

Exposed to the air, apomorphine soon decomposes. Solutions of the drug also rapidly decompose, and as they then may give rise to dangerous symptoms one should always use fresh solutions, preferably those made from hypodermic tablets obtained from some reliable source. It occurs in two forms: the crystalline and the amorphous. Hare[1] says that the amorphous form is dangerous and should never be used. Two of the largest and most reliable manufacturing chemists of this country take exception to this statement and sell both forms, and say that the indications for use and the dosage of both are identical, and that as the amorphous form is a more potent hypnotic it is to be preferred when the hypnotic effect is sought. Five equally responsible firms, in order to be on the safe side, make only the crystalline form, the form which I have used in all my cases. In the preparation of fine alkaloids the most effective method of purification is by submitting them to crystallization. Any impurities which may be present remain in the mother liquor. Hence I would strongly advise that only the crystalline form be used, and that in ordering the drug the physician specify the form desired, for when apomorphine is ordered, and neither form is specified, it is the usual custom of both wholesale druggists and apothecaries to supply the amorphous form, as it is much cheaper.

To Dr. Charles J. Douglas[2] of Boston belongs the credit of first calling the attention of the medical profession to the fact that apomorphine in non-emetic doses is an exceedingly valuable hypnotic. He said: "There is, however, one harmless remedy that will produce sleep in a few minutes, even when the patient is suffering with the wildest delirium. That remedy is apomorphine. . . . While its value has remained so long unrecognized by the profession, yet in point of fact there is no hypnotic in our materia medica that is at once so prompt, so safe, and so sure. . . . . It saves time; minutes as compared to hours."

About three years after this important announcement was made, Coleman and Polk,[3] acting upon Douglas's suggestion, conducted an interesting and highly instructive series of experiments with apomorphine in the alcoholic ward of Bellevue Hospital. They tried the drug in three hundred cases, and sum up their results as follows: "From our own observations we are convinced that apomorphine in small or moderate doses, given hypodermically, possesses definite sedative and hypnotic properties. . . . In 'ordinary drunks,' therefore, apomorphine hydrochlorate may be regarded as an efficient and safe hypnotic in doses of 1/30 to 1/10 grain hypodermically administered, producing a sleep which lasts from several hours to all night."

Several other observers, notably Quehl,[4] Reichert,[5] Bordier,[6] Routz,[7] Challand and Rabow,[8] Bourgeois,[9] Gellhorn,[10] Tompkins,[11] and Lewis,[12] have testified to the value of apomorphine as a sedative and hypnotic, and the consensus of opinion is that the sleep induced is calm, restful, and restorative, closely approaching that of normal sleep, and that the use of the drug is not attended by any unpleasant after effects.

While several cases of death following its use have been reported, Boyer and Guinard,[13] who have carefully investigated this phase of the subject, claim that the untoward results were always due to impure preparations.

In the treatment of acute alcoholism I have employed apomorphine hydrochlorate very largely and with such uniformly satisfactory results that I can most heartily indorse the statements of Douglas, Coleman, and Polk. In my hands it has proven to be a prompt, powerful, and safe hypnotic, second to none in securing quiet and sleep in acute alcoholism.

In moderate doses apomorphine stimulates the heart and slightly raises the blood pressure, while in large doses it is somewhat depressant. The depressant effect is not by any means as marked as that following the use of most powerful hypnotics, especially chloral, and it soon passes off.

A very few minutes after administering an emetic dose by hypodermic injection, vomiting occurs, due to the action of the drug upon the vomiting center in the medulla. Just before vomiting the pulse is weakened and increased in frequency, and after vomiting ceases it becomes stronger and slower, often stronger and slower than it was before the injection was given. Vomiting is preceded by salivation and slight nausea. It may occur only once, or be repeated several times. Very soon after the vomiting subsides, a matter of a few minutes in most cases, the patient falls into an apparently natural sleep, and may sleep for from two to eight hours, awakening refreshed, sober, and rational in most cases. Douglas says: "This remedy shuts off the 'stream of consciousness' with valuable precision, and when this is once done the patient will usually continue to sleep without further assistance until the demands of tired Nature are satisfied."

In treating periodical dipsomaniacs in all stages of the attack I have found apomorphine in full dose of inestimable value, and am convinced that it has been the means of ending the attack in many instances. During the attack this class of patients, as you well know, have but one thought, one aim, one desire—liquor. The demand for the so-called stimulant is a veritable imperative conception. Apomorphine compels sleep, and when the patient awakens his chain of thought has been broken and the attack is over in many cases.

In all acute cases I have found the action of an emetic of some value in sobering the patient and diminishing or abolishing the desire for more drink, and therefore the dose of apomorphine I usually give is 1/10 grain by hypodermic injection, adding 1/30 grain strychnine if the heart is acting poorly. Whenever possible, when giving the injection, I have the patient lying down in bed and have basins in readiness, as the action of the drug is so rapid.

I have never failed to secure the hypnotic effect in alcoholics, and only once failed to secure the emetic effect from 1/10 grain administered hypodermically. This occurred in a young man who had studied medicine, and in whom I used apomorphine with the desired result in a previous attack. From the action of the drug he knew that apomorphine had been given, and when I injected the drug in a subsequent attack he insisted that he would not vomit, and was successful in fighting off the desire to do so. He was unable to remain awake, however.

I have had one case—not alcoholic—in which vomiting did not occur, though 1/5 grain was injected in two 1/10 grain doses within about twenty minutes. The patient was a strong young man, in previous good health, who suddenly became stuporous. I was summoned and reached him within

a few minutes. There being a suspicion of poisoning, I promptly injected 1/10 grain. Vomiting did not occur and the stupor deepened. After waiting about twenty minutes, I again injected 1/10 grain, and, obtaining no result, had him removed to the hospital. He awakened after several hours and went home. While no positive diagnosis was made, I am inclined to believe that the case was one of *grand mal*.

One need not give emetic doses in order to secure the hypnotic effect. In many cases 1/30 grain given hypodermically will be found sufficient to induce sleep. If the general condition of the patient is fair the dose may safely be repeated in about three hours if necessary, as the drug is not cumulative in its action. A non-emetic dose (1/30-1/20 grain) may also be given a few hours after a full dose, if it be desired to prolong sleep or keep the patient quiet. Occasionally vomiting follows the use of doses as small as 1/30 grain; more frequently slight nausea is experienced.

If it be deemed advisable to prolong the sedative effect by bromides, chloral, or similar drugs, it will be found that smaller doses will suffice than are ordinarily required. This is a point of no little importance considering that all such drugs depress the heart.

When administered by mouth the drug cannot be relied upon. Vomiting does not follow the taking of a full dose, and sleep is but rarely secured. A sedative effect, however, is sometimes obtained.

As a hypnotic in acute alcoholism, apomorphine possesses a decided advantage over such drugs as bromides, chloral, sulphonal, trional, and paraldehyde in being available for hypodermic use and insuring prompt action. Valuable time is saved and the wishes of the patient can be disregarded. It is especially of value in enabling one to dispense with the use of hyoscine, a drug which we have often been compelled to use when it became imperative to subdue a patient who would not swallow other remedies, or having swallowed them would promptly eject them. I say especially of value in enabling one to dispense with hyoscine because Hicks[14] of Newark, N. J., whose opinion I value, says "hyoscine is a dangerous drug and should never be used; the symptoms following its use are those of insanity. A patient on the border line of insanity can be made insane by hyoscine."

You all know that many alcoholics are "borderliners," in the treatment of whom more than ordinary caution must be exercised.

Eight years have elapsed since Douglas made his announcement, and it is five years since Coleman and Polk published the results of their investigations. Apomorphine has not received the recognition it deserves. On inquiring among my medical friends I have been astonished to find that scarcely any one of them ever heard that apomorphine possesses hypnotic powers, and I have encountered no one who has ever used it as such. Hence this little reminder and plea for its more extensive employment.

214 SOUTH SIXTH STREET.

Pneumonia—Its Successful Treatment.—J. R. Landers declares that the first thing to do in treating pneumonia is to stimulate the glands and absorbents. At the same time the alimentary tract should be cleaned and kept so, in order that it may readily take up the required medicines. The vasomotor system should be balanced, the circulation equalized and balanced, the body tension brought up, and the emunctories opened and kept in this condition. The writer then describes his method. First, one-tenth grain of calomel is given every hour till one grain has been administered. A saline laxative, sufficient to thoroughly wash out the alimentary tract, follows. In order to keep this system clean an efficient intestinal antiseptic is given, such as the sulphocarbolates. Digitalin is given to strengthen the weakened capillaries and to restore their contractile power in order to force the excess of blood out into the general circulation. It is possible that this remedy alone may prevent later stages. Aconitin is given to relax, that is, to overcome vasomotor spasm outside of the diseased lung. Together with digitalin, this restores the tone and contractile power of the capillaries, balancing up the circulation. As a local application, the writer rarely uses anything except the cotton "batten" jacket to cover the entire thorax. He declares that this method will lessen the mortality of pneumonia 80 or 90 per cent.—*The Medical Summary.*

Physiological Action of Tea as a Beverage.—Lauder Brunton believes that tea, when properly prepared and taken in moderation, is both useful and agreeable. The avoidance of danger from impure water is not the only advantage to be gained by drinking vegetable infusions. Tea is a stimulant, and the use of stimulants is almost universal. The effect of tea, coffee, or cocoa seems to be threefold—on the circulation, on the spinal cord, and on the brain. When these substances reach the circulation, the flow of blood through the brain is increased, the brain cells are supplied with extra nutriment, and thought is quickened. It is probable that the brain cells themselves are affected by tea or coffee, so that communication between them becomes more rapid, more complete, and more permanent, than under ordinary circumstances. But it must not be forgotten that these substances tend to keep up mental action when it is not needed. Thus sleep, which restores the tired brain, is prevented. These beverages lessen the sense of fatigue and give a sense of wellbeing and of power, and actually add to the power of endurance. Tea is liable to abuse, and may then bring about most disastrous results. Tea may interfere with nutrition by lessening the feeling of hunger, by rendering food less digestible, and by interfering with the digestive power of the stomach. The different kinds of tea vary in the amount of tannin which they contain. The leaves should never be boiled or stewed. Boiling water should be poured on the leaves, and after standing for a few minutes should again be poured off. Taken with meat, it toughens the fiber. Hard water and water containing iron do not make good tea. A pinch of bicarbonate of soda, when hard water is used, improves the infusion. Tea, when taken in excess, may produce the most serious nervous symptoms and facilitate, if it does not actually produce, mental degeneration.—*The Practitioner.*

New York, July 27, 1907.

AN OBJECT LESSON IN CAMP SANITATION.

THERE has been a good deal of adverse comment on the Jamestown Exhibition, and the press reports have in general not been of a character to attract visitors to the show. There is one exhibit, however, outside of the Exhibition proper, yet a part of it, which is well worth a long journey and the attendant expense to see and to study, at least for sanitarians, military officers, and physicians. This is Camp John Smith, where the United States troops are quartered. Here, says a correspondent of the *New York Times* of July 21, upon what a few months ago were peanut fields interpenetrated by marshes lying only a few feet above tide level and half a mile or so from the shore of the Chesapeake Bay, are encamped in the open and in the full glare of the sun a regiment of regular infantry, a battery of artillery, and a squadron of cavalry. A better place could hardly be selected for a midsummer camp, for the encouragement of malaria, typhoid fever, and dysentery, for flies and mosquitos, the carriers of two at least of these infections, love nothing better than such a place. But these pests are conspicuously absent from the camp, although they swarm in the adjoining militia camp and the kitchens of the restaurants within the grounds hard by, and this in spite of the fact that the horses of the cavalry and artillery are stabled not fifty yards from the quarters of the men. The mess shelters and kitchens are all screened with wire netting (a precaution which excited the risibles of Mr. Poultney Bigelow when he was inspecting the Panama Canal in thirty-three minutes more or less), the tents are also screened, and over each bed is hung a mosquito bar under which each man and officer must sleep under pain of court-martial. The absence of flies in any number is due to the fact that there is nothing about for them to feed upon or breed in. Just outside the camp is a crematory in which every particle of garbage and refuse is consumed twice a day. There are some mosquitos, hence the necessity of mosquito bars over all the beds, but their number is kept down partly by draining every part of the adjacent swamp which can be drained, and partly by oiling at frequent intervals all the pools and puddles that cannot be drained away. All the water used by the soldiers is boiled, and appliances for this purpose form a part of the furniture of each kitchen.

The proof of the effectiveness of these sanitary precautions, the minuteness of which might be ridiculed by the uninstructed, is to be found in the fact that the morbidity of the troops is only about three per cent., and this in a military camp pitched in a malarious swamp in a region which is no stranger to typhoid fever. As yet there has been not a single case of this disease among the troops in Camp John Smith. The admirable condition of this camp, the *Times* correspondent very justly says, is directly attributable to the energy, activity, and foresight of the Chief Surgeon, Major Charles E. Woodruff, though he is disposed to give the credit to Dr. Jones, his assistant, upon whom much of the routine executive work has fallen.

Major Woodruff has evidently been given a free rein as regards the sanitation of this camp, and what he has accomplished is worthy of the attention of military authorities everywhere. Only nine years ago the country was horrified to learn that the greatest mortality in the Spanish war was at Chickamauga, a thousand miles beyond the reach of Spanish bullets, where patriots who had volunteered to defend their country died by scores from a preventable disease, simply in consequence of neglect of the most elementary sanitary precautions. Who was responsible for this fearful loss of life has never been officially revealed, and it is not necessary now that it should be, but if the object lesson furnished by Major Woodruff at Camp John Smith is taken to heart by our military authorities, and the recommendations of the medical officers of the army are in future heeded, the chief mortality in our next war will be from bullets and not from microbes.

MEDICAL SCIENCE AND THE DEATH-RATE.

MODERN sanitary methods combined with increased medical and surgical knowledge and skill have lengthened human life to a very appreciable extent, and in all civilized countries the population is largely swelling. In some countries a greatly diminished birth-rate has assisted to keep the numbers within reasonable bounds, while in other lands the population is growing to such a degree as to be almost an economic menace.

Great Britain is an excellent example of the former conditions and Germany of the latter. Recently the decennial report of the Registrar-General for England of births, deaths, and marriages has been issued dealing with the mortality in that country in the ten years 1891-1900. Dr. Tatham, the Registrar-General, has shown in this report that the congratulations which have been expended on the decreasing death-rate of England are not altogether justified if the matter be thoroughly considered. He has pointed out that there is an interdependence between the birth-rate and the death-rate which has an important bearing on the figures. The age distribution of the sexes has been materially altered with the decline in the birth-rate, the proportion of people of the more robust ages among the total living has increased, while the percentage of children has become less. Thus the mortality rate for England of 22.28 for the ten years 1841-1850 falls to 21.74 per 1,000 if it be calculated on the age distribution of the present day.

When, however, all these facts have been taken into consideration, there is a very considerable bal-

ance which must be credited to medical and sanitary science. The report of Dr. Tatham makes clear that the past forty years have witnessed an indubitable fall in the mortality of both sexes in England, this decline amounting to 3.55 per 1,000 population. The death-rate among females is less than that among males in every case. It is in regard to infant mortality that medical science has, so far, exhibited the greatest inability to effect marked improvement. The Registrar-General, referring to this point, said: "The health of the adolescent, as well as of the adult portion of the community, has shown a steady improvement in 1891-1900 as compared with preceding years. When, however, the mortality of infants in their first year of life is considered, we are met by the sad reflection that the improved conditions affecting adult life have not been shared by this most sensitive portion of the community." Many of the English agricultural counties contain extensive areas in which the deaths of infants under one year average less than 10 per cent. of the births. There are other and chiefly industrial counties, such as Lancashire, that contain large areas in which the waste of human life is twice as great as it is in the rural areas. In short, urban residence is immensely more deadly to infants than is rural life.

One of the most interesting features of the report is that which discusses the mortality from tuberculosis. It is pointed out that in the past forty years there has been a remarkable fall in the deaths from the various forms of tuberculosis. In the ten years 1851-1860, 3,457 deaths were set down to this cause for every million people living; in 1891-1900 the figures had fallen to 2,010, a decline of 42 per cent. Cancer, on the other hand, though a less frequent cause of death, has shown in England an alarming increase. In forty years the death-rate from this disease among males has trebled, and among females it has doubled.

In the United States medical science and sanitary methods have shown just as great improvement as in England, with equally gratifying results. Here as there, however, infant mortality in the cities is still very large, and must be met by better conditions of living, chief of which is more nourishing food, signifying an improved milk supply.

Tuberculosis in America has decreased to as great an extent as in England, and cancer has increased in a like degree. On the whole, this country is in a far better condition as regards healthy living than is England, on account of its size and because urban life is not nearly so general, but at the same time the situation in this respect is susceptible of much improvement, and especially in the big cities. Medical science in all civilized countries has lengthened human life, and bids fair to ward off death to a yet great[er] extent. It is probable, indeed, that we are on the threshold of some remarkable discoveries tending in this direction.

SYPHILIS AS A CAUSE OF STOMACH DISEASE.

In the study of diseases of the alimentary canal, excepting those of a restricted portion at either end, the importance of syphilis as an etiological factor has received but scant attention. In a recent communication, F. D. Bird (*Surgery, Gynecology, and Obstetrics*, May, 1907) states that a more careful study of the subject will show that syphilitic lesions in the hidden portions of the alimentary canal occur to a greater extent than is ordinarily believed. A syphiloma of the stomach may or may not be combined with ulcer and there may or may not be infiltration of the surrounding tissues. But if a tumor can be felt and an exploratory laparotomy is made, a search should always be made for other evidences of syphilis in the abdominal cavity. The liver, the spleen, and the peritoneum afford confirmatory lesions if the growth is specific in character, and the exploratory incision should be made large enough to permit of examining the abdominal contents by sight as well as by palpation. The cancer-mimicking propensities of syphilis may lead to a radical operation in a given case because the numerical chances are believed to be against specific disease in this region. Gastrectomy may even be performed and then, if the tumor prove to be a syphiloma, an unnecessary operation will have been performed in a subject whose long continued toxic condition constitutes a bar to normal healing.

Bird has personally noted a number of instances in which this has occurred and in doubtful cases, where the involvement of the stomach is extensive and only a gastrectomy would suffice, he advises a microscopical examination of a portion of the growth as the only rational procedure. He considers that the possibility of a second operation, in case cancer is present, does not offer a worse prospect to the patient than cutting out his stomach when medicine would have effected a cure. The fact that supposed cancerous cases often improve to a marked degree after a gastroenterostomy, performed because the tumor precluded a satisfactory gastrectomy, is due in the writer's opinion to the syphilitic character of the lesion. There are a number of other features connected with these cases to be considered. A cancer or other malignant growth may easily be engrafted upon a previous syphilitic base in the stomach or intestine, just as in the mouth, of which a number of undoubted instances have been noted. The writer strongly urges that syphilis be taken into consideration as a possible cause of stomach disease, not as a curiosity, but as the explanation of many cases of obscure gastric disturbances.

Successful Removal of a Tumor of the Hypophysis Through the Nose.

By reason of their situation and anatomical relations tumors of the hypophysis are especially destructive in their effects and also difficult of removal. Nevertheless, operative relief, principally of a palliative character it is true, has been attempted in a small number of cases, with varying results. The usual mode of approach is from the cranial convexity, but a case in which access to the growth was obtained and successful removal accomplished through the nasal cavity has been reported by Professor Schloffer in the *Lancet* of June 1, 1907. The patient was a man thirty years old, suffering from constant headache, with bitemporal hemianopsia and rapid loss of hair from all

parts of the body. *X*-ray examination disclosed enlargement of the hypophysis. Speedy relief without extensive operation being indicated, the nose was freed from its attachments and turned to the right. Next the turbinated bones were removed and the septum excised, hemorrhage being checked by plugging. An opening was made in the inner wall of the orbit and the optic foramen exposed. The inner wall of the maxillary antrum and the nasal process of the upper jaw were broken away. The ethmoidal sinus was then cleared out and the sphenoidal cavity opened. After a lamina of bone that now came into view had been perforated, a soft, friable, bluish tumor could be seen. This was in great part carefully removed, but a portion had to be left in order to avoid injury to the dura mater. A large quantity of cerebrospinal fluid escaped. The cavity in the sella turcica was plugged with gauze dipped in balsam of Peru and a similar gauze drain was packed in the opening at the base of the skull. Both drains were brought out toward the nose, which was replaced and carefully fixed in position with sutures. They were left in place for nine days and were not renewed. Cerebrospinal fluid continued to escape at the tip of the nose every few minutes for several days. The headache vanished completely, but the hemianopsia persisted. In other respects recovery was complete five weeks after the operation and the hair began to grow again. Histological examination of the removed parts disclosed the structure of an enlarged hypophysis. The ease with which the gland was reached, the small amount of hemorrhage, and the absence of postoperative meningitis are pointed out as noteworthy features of the operation. The case is unique in the character of the growth, in the mode of approach, and in the result of the operation.

The Nature of Heat Stroke.

An interesting suggestion in regard to the nature of heat stroke, or at least that form of the condition accompanied by hyperpyrexia, is made by Senftleben, a staff surgeon in the German army, in the *Berliner klinische Wochenschrift* of June 24 and July 1, 1907. As the result of his observations on numerous cases of insolation and heat prostration among the troops he offers the following theory as to the manner in which the various phenomena of the affection are brought about. Owing to the excessive cutaneous and respiratory elimination of water attending prolonged exertion at high temperatures a condition of hemoglobinemia is induced, and the presence of hemoglobin in the blood plasma causes destruction of leucocytes with the liberation of great quantities of fibrin ferment—a sequence of events that has been demonstrated by experiments on animals reported by numerous authors. The sudden setting free of the fibrin in the circulating blood leads to abrupt rises of temperature, while at the same time through the occurrence of more or less extensive coagulation, especially in the pulmonary capillaries, the circulation is greatly impeded. Less and less blood traverses the lungs and the arterial system is insufficiently filled; the vascular tonus falls until finally all of the organs, including the brain, cease functionating and death ensues, not so much through heart failure, as is often alleged, but through cerebral failure. In mild cases the train of destructive changes does not proceed far enough to exceed the body's powers of adaptation. The view that heat prostration is a form of autointoxication is not altogether new, though the present theory explains its nature in a somewhat novel fashion. At any rate, the author's suggestion that the sudden cessation of previously abundant perspiration is to be regarded as a danger signal is a good one, as well as his recommendation that the excessive loss of body fluids should be compensated by adequate drinking of water. The treatment he recommends in addition to the usual measures to control the hyperpyrexia and the respiratory and cardiac manifestations consists essentially in venesection and the infusion of saline solution, measures that have already been found empirically to be of value.

Gastric Therapeutics.

Sufferers from disorders of the stomach will no doubt be more pleased than disappointed to learn that a recently much heralded plan of treatment for such ills appears to offer little of real utility, and that the somewhat unesthetic mode of medication involved is not likely to be widely recommended. A number of authors have written enthusiastic reports on the results obtained in various affections of the stomach, particularly such as are accompanied by a deficiency or absence of hydrochloric acid secretion, by the administration of gastric juice obtained from the dog and also from the pig. These encomiums have not been generally corroborated, however, and a recent observer, in order to settle the question of the utility of this method of treatment, has administered human gastric juice. This was obtained from a patient suffering from gastrosuccorrhea, whose fasting stomach daily yielded from 250 c.c. to 600 c.c. of perfectly clear, highly acid juice. From a teaspoonful to a tablespoonful of this secretion was administered four times a day before eating during a period of five or six weeks to six patients with various forms of dyspepsia. Although it is stated that the remedy was taken without distaste, the improvement produced was no more than might be expected to follow the dietary regulations, etc., that the patients also observed. Rosenberg, the observer in question, therefore concludes (*Münchener medizinische Wochenschrift*, June 25, 1907) that this plan of treatment is not promising, and even goes so far as to deny that much is to be expected from the administration of diluted hydrochloric acid in any quantity that patients can be persuaded to take.

The Duodenal Sphincter.

Two years ago Ochsner, in a paper read at a meeting of the American Surgical Association, called attention to a collection of muscular fibers in the duodenum, from 2 to 4 cm. below the entrance of the common duct, which he regarded as a sphincter of this portion of the intestine, and to which he was inclined to attach considerable importance. The correctness of this finding is disputed by Walter M. Boothby in the *Boston Medical and Surgical Journal* of July 18, 1907, who examined the duodenum in nearly forty subjects in the Harvard Medical School and Boston City Hospital. Some of these were studied macroscopically, others were examined microscopically, but in none could any structure be found suggesting a sphincter muscle. Boothby concludes that the musculature of the duodenum (especially the circular layer) presents certain irregularities in its thickness, but these irregularities are slight as compared with the average thickness of the muscle, and, compared to a true sphincter, the pylorus, are insignificant. In short, he found no grouping of circular fibers in the duodenum which could be considered an anatomical sphincter muscle.

News of the Week.

The Bill to Prevent Substitution in Prescription Compounding, which was passed recently by the Legislature of this State, has been signed by the Governor. This bill amends Section 401 of the penal code relative to certain offenses connected with the dispensing and sale of drugs and medicines. It provides that "Any person who, in putting up any drug, medicine, food, or preparation used in medical practice, or making up any prescription, or filling any order for drugs, medicines, food, or preparation puts any untrue label, stamp, or other designation of contents upon any box, bottle, or other package containing a drug, medicine, food, or preparation used in medical practice, or substitutes or dispenses a different article for or in lieu of any article prescribed, ordered, or demanded, or puts up a greater or less quantity of any ingredient specified in any such prescription, order, or demand than that prescribed, ordered, or demanded, or otherwise deviates from the terms of the prescription, order, or demand by substituting one drug for another, is guilty of a misdemeanor." The bill expressly grants to the druggist the right (except in the case of a physician's prescription) to recommend the purchase of some other article than the one called for, but he must not substitute such article without the knowledge and consent of the purchaser. This bill was introduced in the Senate by Mr. Page at the instance, we understand, of Mr. Charles Roome Parmele. The previous law forbidding substitution, of which this is an amendment, was practically of no force, since it was not possible to punish alteration of the physician's prescription, unless it could be proved that human health or life had been endangered by such alteration. The law goes into effect on September 1 of this year.

Army and Navy Union in Favor of the Canteen.—The Army and Navy Union, at its meeting held in Washington on July 18, adopted the following resolutions in favor of the restoration of the canteen: "That we desire to go on record with the officers and men of the army, with President Roosevelt and Secretary Taft, with the Spanish veterans and many other patriotic organizations in favor of the restoration to the army and to Soldiers' Homes of the canteen as it was operated prior to 1901. That our own experience has shown beyond question that the sale of beer and light drinks in the army canteen was a veritable temperance measure; that it aided in promoting the moral welfare and comfort of the men in the post and camps, and that no greater blow to genuine temperance was ever struck than when the law was repealed. That we believe Congress should have the courage to meet this question squarely and fairly, and not be influenced as in the past by the theories of persons who have had no actual experience with army and navy life. We therefore direct the officers of this organization to take whatever steps may be necessary to urge Congress to restore the former law as to the canteen, believing that we are acting not only for the good of our soldiers, but likewise in the interest of temperance and moderation."

Third International Sanitary Convention.—The Third International Sanitary Convention is to be held in the City of Mexico on December 2 to 7 of this year. The two preceding conferences were held in Mexico in 1902, and in Rio Janeiro last year. The program provides that each delegate shall bring a paper relating to the nation he represents and covering a report on the existence of transmissible diseases that may prevail in its territory, especially with reference to bubonic plague, yellow fever, cholera, malaria, beriberi, and trachoma. A request is made for information as to the methods adopted for the prevention and stamping out of such diseases; also reports on the condition of ports and sanitary police laws. The transmission of yellow fever and the means to be used in combating the stegomyia mosquito, the tuberculosis question, and various administrative measures, will also come up for discussion. Surgeon-General Walter Wyman is chairman of the International Sanitary Bureau.

Pure Foods and Drugs in Spanish America.—The Board of Food and Drug Inspection has decided that, under the Pure Food law, products meant for foreign consumers are not subject to domestic regulations such as relate to preparations of drugs, chemicals, dyes, and preservatives with food, so long as they comply in this respect with the food laws of the countries to which they are exported. Dr. A. M. Fernandez de Ibarra of this city, the American correspondent of a number of medical journals in Spanish-speaking countries, states that he has warned the readers of these journals that many impure drugs and food products are being sent to Spanish-American countries where pure food laws do not exist. The Argentine Republic has recently passed a law similar to ours.

Hospital Internes Suspended.—Charities Commissioner Hebbard has suspended for terms of one and two months each four of the internes of the Kings County Hospital and Bradford Street Hospital for their connection with an experiment in skin grafting carried out on two puppies. The Commissioner holds that the performance of such experiments in public hospitals tends to impair their reputation for humanity, and that those who took part in them were guilty of a serious indiscretion.

Mosquito Extermination in New Jersey.—As a result of the ditching that has been done in the Hackensack Meadows, the low lands between Newark and Elizabeth, and other marshes in the neighborhood, together with the oiling of stagnant pools, the mosquito pest has been reduced by what is estimated as at least three-quarters.

Street Cleaning at Night.—Street Cleaning Commissioner Bensel is about to put into execution a method of street cleaning which is in general use in large European cities. Instead of doing most of the work as at present during the hours when the traffic is heaviest, the bulk of the cleaning and removal of ashes and garbage will be carried on at night, when the streets are comparatively deserted.

Garbage Barrels for Holding Food.—The Central and Federated Union of the Coopers of New York, at a meeting last week, passed a resolution expressing its disapproval of the practice of certain "soulless individuals" who are alleged to buy for three and five cents the garbage barrels emptied at the New York dumps, repair them, and use them again for the packing of meat, vegetables, flour, etc., for public consumption. Copies of the resolution have been sent to Health Commissioner Darlington and Mayor McClellan.

Peace Conference Adopts Red Cross Proposal.—At the meeting of The Hague Peace Conference on July 20 a report was read by the French delegates relating to the adoption of the Red Cross regulations in naval warfare. The Persian and Turkish delegates made their usual observations setting forth the impossibility of their accepting the cross as an emblem, but after further discussion the Red Cross proposal was approved.

Typhoid Fever in New Jersey State Hospital.—Seventy cases of typhoid fever, with eleven deaths, have been reported from the New Jersey State Hospital for the Insane at Trenton. An investigating committee has found that the sanitary conditions in the institution are very bad and demand radical reforms.

Typhoid Fever at Tuskegee.—An epidemic of typhoid fever is reported to be prevailing at the Tuskegee Normal Institute. Up to July 22 there had been twenty-seven cases and two deaths.

Smallpox on Ocean Liner.—Owing to the discovery that the child of a second cabin passenger on the steamship *Koenigin Luise,* which reached this port last week from the Mediterranean, was suffering from smallpox, the ship's surgeon vaccinated several hundred of the passengers and crew who had not been so protected within a reasonable time.

Whooping-cough is very prevalent along the Jersey coast and large numbers of children have been infected in the summer colonies at Long Branch, Monmouth Beach, and Seabright. The epidemic is believed to have started in the negro and Italian quarters of East Long Branch, though there were also many cases at Asbury Park before the season opened.

Another Gift by Mrs. Sage.—Mrs. Russell Sage has given $125,000 to the Association for the Relief of Respectable Aged Indigent Females in the City of New York. The home of the Association, at 104th street and Amsterdam avenue, is being extensively enlarged, and when the addition is completed its capacity will be increased from 90 to 270 beds.

Bequests to Charities.—By the will of the late Isidor Wormser filed for probate last week, the Mount Sinai Hospital and the Hebrew Orphan Asylum are to receive $2,500 each, the United Hebrew Charities Association of this city $2,000, and the Home for Aged and Infirm Hebrews, the Montefiore Home for Chronic Invalids, the Roman Catholic Orphan Asylum, the Hebrew Technical Institute, the Educational Alliance, and the Tuskegee Institute, $1,000 each.

Connecticut Tuberculosis Commission.—A commission to investigate tuberculosis in the State of Connecticut has been appointed by Governor Woodruff with the following medical members: Dr. J. P. C. Foster of New Haven, Dr. O. LaRue of Putnam, Dr. Stephen J. Maher of New Haven.

American Medical Editors' Association.—At the thirty-ninth annual meeting of this organization held in Atlantic City, sixty-four new members were admitted. The following were elected as officers: *President,* C. F. Taylor, M.D., Philadelphia, Pa., editor of the *Medical World; Vice-Presidents,* Kenneth Millican, M.D., St. Louis, editor *St. Louis Medical Review,* and H. E. Lewis, M.D., New York, managing editor of the *International Journal of Surgery; Secretary and Treasurer,* J. MacDonald, Jr., M.D., New York, managing editor of the *American Journal of Surgery.*

Lake Keuka Medical and Surgical Association.—The eighth annual meeting of this organization was held at Grove Springs, Lake Keuka, July 25 and 26, 1907, under the presidency of Dr. J. E. Walker of Hornell.

Connecticut State Board of Health.—At a meeting held in Hartford the following officers were elected: *President,* Prof. W. H. Brewer; *Treasurer,* Dr. J. H. Townsend; *Managers of County Homes,* Dr. E. K. Root, Hartford and Middlesex; Prof. W. H. Brewer, New Haven; Dr. J. H. Townsend, New London; T. H. McKenzie, Fairfield; Dr. A. W. Phillips, Litchfield; Dr. A. J. Wolff, Windham; Lewis Sperry, Tolland.

Lamoille County (Vt.) Medical Society.—At the meeting of this organization held in Morrisville on July 12 officers were elected as follows: *President,* Dr. G. L. Bates; *Vice-President,* Dr. S. G. Start; *Secretary,* Dr. G. C. Rublee; *Treasurer,* Dr. J. C. Morgan.

Iowa Union Medical Society.—At the meeting of this society held in Iowa City on July 10, Cedar Rapids was selected as the next meeting place and officers were elected as follows: *President,* Dr. J. M. Ristine of Cedar Rapids; *Vice-Presidents,* Dr. E. N. Brown of Marengo, and Dr. S. H. Watson of Blairstown; *Secretary,* Dr. A. Crawford of Mount Vernon; *Treasurer,* Dr. George P. Carpenter of Cedar Rapids.

Death of Professor Grancher.—Dr. Joseph J. Grancher, a member of the French Academy of Medicine and Professor of Children's Diseases in the University of Paris, died in that city on July 15 from pneumonia.

Obituary Notes.—Dr. John B. Summers died at his home in Milton, Indiana, July 17, from gastric hemorrhage. He had attended to his usual professional duties until five days of his death. He was born at Rising Sun, Indiana, 1841, was graduated from the Ohio Medical College, and later, in 1876, from the Bellevue Hospital Medical College. He had practised in Milton thirty years and had served several years on the Board of Education, and held other positions of trust.

Dr. Charles H. Boardman of this city died on July 17, in his sixty-ninth year. He was a son of the late Rev. Dr. H. A. Boardman of Philadelphia and a graduate of Yale College and the University of Pennsylvania Medical School. He was professor of medical jurisprudence in the University of Minnesota from 1887 to 1890.

Dr. W. W. Robinson of Loveland, Colo., died suddenly of asthma on July 11. He was thirty-five years of age and had practised in Loveland for five years. He was formerly a resident of Anna, Ill.

Dr. William Mazyck of Charleston, S. C., died on July 10, at the age of thirty-one years, after a long illness. He was a graduate of the South Carolina Military Academy and of the Charleston Medical College. For the past four years he had been one of the city physicians of Charleston.

Dr. Hamilton Osgood of Boston died on July 10 in Oxford, Eng., as the result of a long illness. He had made a special study of the therapeutic value of hypnotism, and for some years was associate editor of the *Boston Medical and Surgical Journal.*

Dr. J. H. White of Delaware, O., died on July 13, at the age of ninety years. He was born in Lewis County, N. Y., and received his medical education at the Starling Medical College, Columbus. After his graduation he practised for a time in Warrensburg and in Ashley, and then became a resident of Delaware. In 1890 he gave up active practice.

Dr. Joseph A. Krieger of St. Louis, Mo., died on July 12 after a short illness. He was a graduate of the old Missouri Medical College.

Dr. John Henry Criswell of Marion, O., died on July 14, after an illness of nine months. Dr. Criswell was born in Morrow County, O., in 1850, and was graduated from the Cincinnati College of Medicine and Surgery in 1877. He commenced practise in Caledonia, and in 1884 was made probate judge of Marion County. He then removed to

Marion, and in 1903 was elected to the general assembly of the State.

Dr. Marshall D. Kelly of Nashville, Tenn., died on July 7, at the age of seventy-six years. He was graduated in medicine from the medical department of the University of Nashville in 1857. He first practised in Cornersville, but removed to Nashville about twenty years ago.

Dr. Alfred Wynkoop died at Philadelphia on July 17, at the age of eighty-seven years. He was graduated from the medical department of the University of Pennsylvania. He served as an army surgeon during the Civil War, being for a time assistant at the Chester Hospital. He was later promoted to the position of medical director of the Second Division of the Sixth Army Corps. He participated in the battles of Fredericksburg, Chancellorsville, and Gettysburg. He was honorably discharged at the close of the war with the rank of lieutenant-colonel.

Dr. Edward J. Gallagher of this city was instantly killed in an automobile accident near Jamaica, Long Island, on July 21. He was a native of Brooklyn, and was graduated from the Bellevue Hospital Medical School in 1887. He was fifty-one years of age.

Dr. Edwin J. Russell of Brooklyn died on July 21 as the result of injuries received at the hands of street robbers, by whom he was assaulted while on his way to see a patient in Harlem. He was forty-nine years old, and was graduated from the Homeopathic Medical College about twenty-seven years ago.

Correspondence.

PRIMARY TYPHLITIS WITHOUT APPENDICITIS.

To the Editor of the Medical Record:

Sir:—A year ago[1] I directed attention to the frequency of symptoms which are to-day regarded as those of appendicitis, but are in reality symptoms of typhlitis. To Dieulafoy of Paris also belongs the honor of having supported the claims of colitis against those of the now greatly overburdened appendix. In a very instructive paper in the *Annals of Surgery* for June, 1907, Dr. C. A. McWilliams has again brought this subject before the medical profession and he shows that he and others, during operations and at autopsies, have recognized that the cecum was diseased and the appendix healthy when, unfortunately, an operation had been performed for supposed disease in the latter organ. Howard Kelly, as McWilliams reports, has already found many cases of typhlitis in which there were no evidences of appendicitis. Kaheren states that in a large proportion of cases after the interval operation, the patients suffered from pain and constipation similar to what had been present prior to the operation. It is not claimed that one can decide frequently by the symptoms present before operation between appendicitis and typhlitis and the indications for operation are therefore similar. Nevertheless, the foregoing statement should make it evident that "ordinary cases of colitis of the catarrhal variety probably are often confounded with appendicitis and operated on as such."[2]

This being admitted, would it not be wiser, as a rule, to restrict one's operations to (1) cases of acute perforation, (2) cases where an abscess has formed and is limited by adhesions—when it is a very simple matter to let out the pus and properly drain. In the former cases, of course, the sooner operation is done the better, and yet even in these instances mistakes arise and occasionally there is no perforation, as shown subsequently, either because the patient recovers completely in a short time,[3] or because abdominal section demonstrates that it is not present.

Beverley Robinson, M.D.

Westport, N. Y.

[3] I reported such a case some years ago in the Medical Record.

OUR LONDON LETTER.

(From Our Special Correspondent.)

CANCER RESEARCH—ROYAL INSTITUTE OF PUBLIC HEALTH CONGRESS—CONFERENCE ON PURE MILK SUPPLY OF INSTITUTE OF HYGIENE—LORD LISTER—DEATH OF SIR WM. T. GAIRDNER.

London, July 5, 1907.

The Prince of Wales presided on Monday at the sixth meeting of the Imperial Cancer Research Fund. The report mentioned that Dr. Bashford, superintendent, had attended meetings and taken part in discussions in Canada, the United States, and Germany. The museum of the Royal College of Surgeons had been provided with a series of specimens showing the growth of cancerous tumors in mice, with a complete set of histological preparations illustrating their development. The government of Cape Colony had forwarded a report of a committee of the House of Assembly on certain reported cures of a herbal sort, the claims of which could not be substantiated. Dr. Bashford reported that a wide range of research had been maintained and the hopes of advancing knowledge had become more and more centered in experimental investigations. The experiments on living animals continued to be controlled, and the results supported by comparative biological and statistical investigations. These were continued in London and provincial hospitals, in India and in colonies and protectorates. Of 1,806 cases in India 1,513 affected the surface and only 76 internal organs; 335 were in persons living on vegetable diet, 608 on a mixed diet, largely flesh.

In 1889 the Registrar-General calculated the liability of cancer of persons thirty-five years old or older as 1 out of 21 men and 1 of 12 women. The figures for 1905 give the chances as 1 in 12 and 1 in 8. The question of real or apparent increase must wait for further data. But it is noted that cancer as a cause of illness is more rare than infective diseases, as the high case mortality of cancer represents nearly the total cases observed.

The question whether there is a family as well as an individual liability can only be determined on animals of a short life. In mice, by crossing different strains, the concentration of a hypothetical hereditary factor can be obtained and in the course of a few years determine whether there is a family as well as an individual liability to cancer.

Dr. Bashford reported that serious attention had been given to alleged cancer cases brought under notice during the year, but unfortunately it was impossible to assign any value to any of them. The reinvestigation of trypsin has shown it to be incapable of influencing cancer in mice. The financial statement having next received attention, Sir W. Church moved the adoption of the report and remarked on the valuable assistance received from India and other dependencies from which our knowledge of the frequency in various races was increasing and evidence was accumulating that the disease is often associated with native customs and rites irritating the surface. No support was given to the idea that the disease was associated with any kind of diet. In studying the relation of cancer cells to those of the organism in which they occur, an abundant supply of material is necessary, and this year they had obtained and propagated two fresh groups of tumors, viz., certain cancers of the mamma characterized by tendency to hemorrhage, and certain squamous-celled cancers. Further research confirmed last year's statements as to protection conferred by the spontaneous absorption of tumors which had grown for a time against subsequent inoculations of the same strain. The degree of protection was proportional to the amount of tumor tissue absorbed. The immunity is maximal against its own variety, minimal or absent from other strains, showing the change to be intracellular. It was not by modifying the cancer cell, but the environment that the implanted cell in a protected mouse can be hindered or prevented from growing.

Sir Henry R. Swanzy seconded the motion, remarking that, though much had to be learned, substantial progress was being made and they might confidently hope the time would come when they would not only understand the nature and cause, but find an effectual cure of cancer. The report brought out clearly the necessity of experiment and that was most important when opinions were expressed which would frustrate the work which must be near to the heart of every right-thinking man. The Royal College of Surgeons in Ireland, over which he had the honor to preside, was deeply interested in the work and had the utmost confidence in the Fund.

Sir R. D Powell proposed and Mr. Edmund Owen seconded a vote of thanks to the Prince, who in reply remarked that the broad lines of inquiry undertaken by the Fund had doubtless influenced the whole nature of in-

vestigation at home and abroad. It was, he said, recognized that the work was carried on in a liberal spirit, and whatever facts were ascertained were immediately made known. We may gather from the report that the result of the work has been to leave behind certain vague issues which it was necessary to decide in order to clear away doubts and narrow down the issue to a definite line of investigation in which the clew to the nature of cancer must be sought. Good progress has been made and the investigation of reported cures may assure the public that nothing will be neglected to help towards the alleviation of suffering.

The annual congress of the Royal Institute of Public Health has been held this week in the Isle of Man, about 500 delegates attending. Lord Raglan, president, who opened it on Saturday, said this year was specially interesting because the society comes of age in it and because it is the tenth since Queen Victoria became its patron and conferred on it the title of Royal. He was glad to see the King continued the patronage and interest in its work. From a hygienic point of view, he said, we were in advance of other nations. In regard to the progress of medicine, his Lordship spoke of two ideas. The first was pouring things down the sick man's throat until they either killed or cured him, the second that it did not matter to A, B and C whether D died or not; that was his lookout. Those ideas were both exploded and we see that "prevention is better than cure," because the sick man is not only a danger to himself, but to everyone around him. The idea of personal liberty which allowed anyone to spread disease was exaggerated and we are still handicapped with wrong ideas hung on the word liberty. Foreign countries had a great pull in compulsory military service, and young men rejected for armies on account of tuberculosis could be notified to the civil authorities and cared for.

There were sections devoted to preventive medicine, school hygiene, bacteriology, chemistry, and engineering and architecture, in all of which papers were read of considerable interest, but which it is not even possible to outline or enumerate in a moderate space. Let me refer to the Preventive Medicine Section: In that Sir James Barr of Liverpool University delivered the opening address, in which he pointed out many shortcomings. He told the audience plainly that if the money spent on treatment were diverted to prevention of disease and the preservation of health many hospitals might have half their beds unoccupied, dealers in artificial foods and synthetic drugs might find a suitable place in a home for the destitute, and many surgeons and specialists could be spared, while physicians and general practitioners would find better occupation in advising their clientèle as to the preservation of health. He even suggested—rather grimly—that a system might be so perfected that advisers who allowed patients to die should be expected to pay the funeral expenses. From this he passed on to express the opinion that sanitarians had not been more successful because they had confined their attention too much to zymotic disease and the preservation of life rather than the improvement of health. He would encourage the military spirit as the best means of developing the physique and moral grit of the people. He further advocated medical inspection of school children and seeing that the healthy received as much attention as the degenerate. The deaths of children might be reduced by half if parents and the State took sufficient interest in their health.

Mr. Mayo Robson presided at a conference called by the Institute of Hygiene on Monday in reference to the pure milk question. He urged the importance of pure milk to both infants and adults, for if instead of nourishment a poison—dirty milk was that—was given, infant mortality must be excessive. Dr. Thresh said veterinary inspection of cows was required. Milk intended for transmission should be cooled to 40° F. and sent in refrigerating vans. Much contamination took place in the homes of the poor, and therefore education was required. Dr. George Carpenter, as a physician to a children's hospital, accepted an invitation to inspect the dairy company supplying it. He gave some details of the shocking conditions he observed. Dairymen often thought they were doing right to sterilize their milk, but he declared some of them were sterilizing sewage. The editor of the *Dairy World* said the farm described by Dr. Carpenter was by no means a typical one and added it was medical men who had suggested sterilization. Mr. Davies said he had traveled in America, Denmark, France and Germany, and London milk was equal to any. Dr. Lawson Brown attributed all defects to sanitary ignorance. Resolutions were passed in favor of compulsory veterinary inspection, the local board having power to deal with defaulting authorities, and medical officers of health to have fixity of tenure.

Lord Lister was presented last Friday with the freedom of the City of London. In a brief speech he accepted it as "the highest civic honor in the world" and thanked the corporation for the special arrangements made to facilitate his presence, but for which, in his feeble health, he could not have attended to receive the freedom in that historic building. The event recalls that it is more than a century since another great medical discoverer—Dr. Jenner—was presented with the freedom. The leaders of the profession assembled in force to witness the ceremony.

Another great and beloved leader has passed away. Sir William Tennant Gairdner died suddenly on the 28th, aged eighty-two. His long career as a successful physician and valued teacher of clinical medicine to some degree obscures his other eminent qualities and work. He took his M.D. Edin. in 1845 and was awarded the gold medal. In 1850 he was elected a Fellow of the Royal College of Physicians, Edin., and in 1853 began to lecture on clinical medicine in the Extra-Academical School. In 1862 the University of Glasgow gave him the Professorship of Medicine, which he filled until his retirement in 1900. In 1862 he issued his "Public Health in Relation to Air and Water," a record of the first course of lectures on public health ever delivered in Scotland. While residing in Glasgow he was Physician to the Royal Infirmary, the Western Infirmary. He was also elected President of the Edinburgh College of Physicians, the first occasion on which the office had been given to a nonresident. He was physician to Queen Victoria from 1873 to her death, and to King Edward since. He was made K.C.B. in 1898. Edinburgh gave him her LL.D. in 1883. Dublin made him Honorary M.D. and F.R.C.P. in 1887. The F.R.S. and other distinctions were also given him. He long represented Glasgow University on the General Medical Council. Professor Gairdner's "Clinical Medicine," which first appeared in 1862, has been ever since a favorite with students. His "Lectures to Practitioners," published with Dr. Coats in 1888, has also maintained the high position it immediately took. "The Physician as Naturalist" consists of interesting memoirs on the progress of medicine and "the three things that abide" of three addresses to young men—"Faith, Hope, and Love" being the three things—to which he added another addresses to the White Cross Society of Edinburgh University, entitling it "A Faith."

OUR LETTER FROM COPENHAGEN.

(From Our Special Correspondent.)

STERILIZATION OF CATGUT—INCOME OF SWEDISH PRACTITIONERS—DEATH OF PROFESSOR GRUT—CAMPAIGN AGAINST RATS IN DENMARK.

COPENHAGEN, July 4, 1907.

Dr. N. V. Akerblom recommends a method, devised by him, for the sterilization of catgut. The catgut strings, previously wound on glass rings, are placed in a nickel-plated metal vessel containing olive oil, and this oil is slowly heated until its temperature reaches 150° C. Once at this point, it is rapidly cooled down. As a result of this treatment the catgut strings become stiff and hard, but they regain the necessary softness and pliability by subsequent conservation in 92 per cent. alcohol, with an addition of ⅓ per cent. formalin. The bacteriological and practical tests have shown that this treatment makes the catgut entirely aseptic and very tough and resistant, so that fine numbers of it suffice for all work. The ease with which the sterilization is obtained should recommend the method to the busy practitioner.

The yearly income of Swedish public medical officers has been looked into by Dr. Andrew Alfvén. The average income of salary and practice was, for the 242 colleagues that had given the required information, less than $2,000, varying from $650 to more than $4,000. The average cost of the medical curriculum, which in Sweden is very long (eight or nine years), was computed at $4,600. The debts, into which the long and expensive period of study had obliged the students to run, was on an average $3,500. Two hundred and nineteen of these two hundred and forty-two practitioners had answered the question at what age they had paid or thought they would be able to pay this debt; fourteen of them stated that they saw no probability of ever being able to become debtless; thirteen were doubtful, and five named a very remote future; twenty had been freed by lucky casual happenings; ninety-nine had paid the debt (in their case averaging less than $3,000) at the age of 41; sixty-nine (with an average debt of $4,000) hoped to be clear of it when they reached 51. This is certainly rather a dark picture. The statistics concerning the yearly income of practitioners in Stockholm are a little more agreeable to review. Of these 50 per cent. had declared a revenue of more than $2,500; 12 per cent. between $2,500 and $2,000, and 28 per cent. below $2,000.

The death of Professor Edmund G. Hansen Grut has inflicted a heavy loss on Danish medical circles. One of v. Graefe's favorite pupils, the deceased was our first ophthalmologist in the modern sense of the word. He opened his clinic, which was soon to become famous throughout Northern Europe, as far back as 1863, and, in spite of considerable opposition from certain older members of the faculty, he became and remained a university teacher of his specialty during a long series of years. Among the many scientific honors that fell to his lot, and the one which perhaps he esteemed highest, was that in 1889 he was called to deliver the Bowman lecture before the Ophthalmological Society of London.

Our indefatigable legislative body has framed a law of some medical interest. The law, which came into force on the 1st of July, is directed against the rat nuisance. As the diseases, the spreading of which is generally attributed to rats, never or hardly ever occur here, the motives for the carrying of the law have mostly been of an economic nature and prompted by consideration of the important destruction caused by the little rodents. But in countries where rat-caused diseases occur more frequently, it might perhaps be well to take similar measures. The law provides that the State set aside $10,000 a year for the distribution of rat-killing preparations. Further, the municipalities are obliged to pay about 2 cents for every killed rat delivered to the authorities *ad hoc*. Heavy fines threaten those that should begin breeding rats or import them from abroad, with a view to making an easy and agreeable living. The promoters of the cause—there exists here a league against the rat nuisance—believe that they are going to make an Eden without rats of Denmark. It is not impossible that the modest appeal of the law to the lust of lucre of my countrymen will prove more efficient in eradicating the rat evil than the solemn lawsuits and anathemas which, during the middle ages, the ecclesiastical authorities repeatedly directed against rodents, cockchafers, and other dumb criminals.

Progress of Medical Science.

New York Medical Journal, July 13, 1907.

Subcutaneous Rupture of the Spleen.—This subject receives a systematic review from E. Eliot, Jr., who gives the histories of three personal cases, one of which was an instance of serious abdominal lesion after trauma, but without rigidity. In this case retroperitoneal hematoma followed the injury (man struck by motor car and thrown against a lamp-post). The man recovered after operation. The first of the splenic cases was that of a man of twenty-eight years, who had fallen down a shaft. The spleen showed a deep rupture two and one-half inches long, in its phrenic surface. Splenectomy was done and recovery ensued. Case 2 was that of a woman of thirty-four years who fell against an ash-can. Splenectomy was done six hours later, and though she had a very critical postoperative experience, she was doing well when the case was reported. The clinical histories of these two cases are given in detail and cannot be reproduced here. The author calls attention to the fact that nature endeavors to provide a substitute for the loss of splenic reparative power, as is evidenced by a moderate hypertrophy of the lymphatic glands or of the thyroid or of the marrow of the bones, the last mentioned being indicated by a general soreness along the shaft of the long bones. Experimental evidence exists to show that splenectomy in animals increases their resistance power against various infections, but we have no knowledge in this direction as bearing on the human species, although there are several cases on record of infections occurring in splenectomized individuals running mild courses in severe epidemics. In one case there occurred pneumonia six months after operation, and during this whole time there was a considerable increase of large lymphocytes persisting many months after recovery, though previous to the pneumonia the blood count had been normal.

The Craving for Sweets in Diabetic Patients.—A. A. Ripperger says that while the loss of calories resulting from the exclusion of sugar from the diet of diabetics can be easily replaced, still the patient craves sweets, and he notes the recent recognition of the nutritive value of sugar. The only safe substitute is saccharin and the author's paper is largely devoted to a consideration of this substance. He reviews the literature of the question and declares that the restrictions placed on its use in continental countries have been instituted by the cane and beet sugar growers who had feared competition with its consequent lessening of their own revenue. Saccharin has no nutritive value, and clinical experience appears to show that its use as a condiment is attended with no deleterious effects. It will prevent fermentation, but there are other preferable remedies for this object. It does not in any sense cure diabetes. It only satisfies, and that in a perfectly safe way, the craving for sweets. It should not be used in such large doses as to cause repugnance and nausea. Out of twenty-six replies to a circular letter sent out by the author to various physicians twenty-two stated that the respective writers considered saccharin a harmless addition to foods and beverages. One writer was doubtful about the matter and three failed to express any opinion on the matter. The average dose seems to have been about three grains three times daily.

Diagnosis by the Nose.—The sense of smell in diagnosis receives an elaborate consideration from E. C. Hill, who reviews briefly the physiology of olfaction and reproduces Quaardemaker's classification of odors. He then discusses the characteristic odors emanating from the skin in health and disease, the breath, sputum, vomitus, and gastric contents, feces, urinogenital discharges, and aspirated fluids.

Journal of the American Medical Association, July 20, 1907.

The Salicylates in Lichen Planus.—M. B. Hartzell finds that in a minority of cases of lichen planus, in which the arsenic treatment fails, the salicylates either alone or in conjunction or alternating with arsenic, are of good service. Four cases are reported of patients thus treated with salol and salicylates of lithium and sodium. While the number of cases is inconclusive to a certain extent, there seems to be sufficient evidence that the salicylates are sometimes of value, especially for the relief of itching and in cases where arsenic either fails or actually aggravates the condition. Hartzell also describes several unusual eruptions of lichen, such as circles and segments of circles, slightly elevated discs, and band-like papules instead of the ordinary diffuse form. One type mentioned as perhaps the rarest and most interesting is that where blebs accompany the usual flat-topped angular papules characteristic of the disease. These were present in one of the cases reported, and the author suggests the possibility of their being the result of traumatisms caused by the patient scratching himself.

Ulcerative Keratitis Caused by Yeast Cells.—G. F. Keiper and S. Burrage report a case of deep ulcer of the cornea occurring in a man employed by a strawboard manufacturing company, which was cured by calomel and atropine with hot water applications. The whitish growth covering the ulcer was cultivated and numerous slides prepared from the culture; the stain used was methylene blue. Three kinds of organisms were found: A sarcina, in all probability *Sarcina lutea*, a small, unidentified bacillus producing a pink-colored growth, and a diplococcus. Inoculation experiments on guinea pigs produced corneal ulceration in all cases in which cultures of the blastomycetes were used. Further experiments are being made which seem to promise results of interest. The paper is offered as only a preliminary report.

The Use of Paraffin Injections Near the Eyes.—A. E. Davis gives case histories of two patients showing the danger of the employment of paraffin injections near the eyes. In the first case the paraffin, injected near the root of the nose to correct a deformity, caused an immediate swelling of the upper eyelid, with marked inflammatory reaction, keeping the eye closed for six weeks, followed by permanent ptosis, the vision and movements of the eyeball remaining normal. There was a lump in the forehead near the root of the nose which was also the result of the injection. Operation two years later removed from the eyelid a mass of connective and fibrous tissue with particles of paraffin and completely relieved the ptosis. The second case was that of a boy of seven, who had had his right eye enucleated on account of an injury, and the capsule of Tenon filled with paraffin. He did well for nearly a year, then the artificial eye began to squint inward and symptoms of sympathetic irritation appeared in the other eye, together with headaches. The capsule was found empty and a solid ball of paraffin, 7x5x3 mm. in size, together with a smaller piece, was removed from near the apex of the orbit, and the symptoms quickly disappeared. It is supposed that during the first operation the capsule must have been punctured, the paraffin escaping pressed on the optic nerve and gave rise to the symptoms observed. Davis reviews the literature of similar accidents and thinks the dangers have been sufficiently demonstrated to make a more thorough investigation of the subject desirable.

The Cause of Infantile Atrophy.—A. H. Wentworth suggests as a possible cause of infantile atrophy a de-

fective correlation of the several digestive organs, stomach, intestines, pancreas, and liver. This hypothesis is based on the discovery of Bayliss and Starling of secretin, originating in the small intestine and passing from it through the blood to the pancreas, and to some extent to the liver, which organs are stimulated by it to secrete. He reports experiments on cats made to ascertain the effect on the pancreatic secretion of the secretin obtained by Bayliss and Starling's method from the cadavers of atrophic, new born and other infants. The tabulated results show that the material obtained from the intestines of atrophic infants possessed little or no power to stimulate the flow of pancreatic juice in the cat, indicating either a lesser strength or quantity of secretin present. The secretin from well-nourished infants and children, on the other hand, always caused activation of the cat's pancreas. He thinks it very unlikely that the diminution of secretin can be due to inanition, as suitable food restores the functions rapidly before the general marasmus of the infant has been bettered. He has also experimented to ascertain as far as possible how much it can be due to digestive disturbances, etc., and while his investigation is not yet finished, he is inclined to offer the following hypothesis as the result of the research thus far to explain the cause of infantile atrophy: The digestive functions of the very young infant are not activated because it does not receive the only food capable of activating them, viz., mother's milk. This leads the stomach to secrete an inadequate gastric juice, and the duodenum is therefore not stimulated to form normal secretin. The defective secretin insufficiently stimulates the pancreatic secretion, and leads probably to as yet unstudied disorders of the function of the gut lower down. What renders the milk specific in this way is now engaging his attention and he hopes to be able to answer it in the future. It is possible that it is due to some hitherto overlooked specific substances or to certain hitherto disregarded factors in chemical composition.

Benign Melanosis.—A case of melanotic abdominal tumors with pigmentation of urine, milk, and sweat, is reported by J. C. Stewart. The patient has been in good health for fifteen years after the diagnosis of multiple melanotic sarcoma had been made and operation suspended on account of the apparent hopelessness of the condition. The patient has passed through two normal pregnancies, following the last of which, as well as after the operation, there was temporarily black pigmented milk from the breasts, and melanuria. The probable explanation given is that the original cyst was either a dermoid with great overproduction of pigment, or that a parovarian cyst became the seat of repeated hemorrhages and filled with changed blood pigment. Against this latter, however, is the fact that the urinary pigment was apparently melanin, and not changed blood pigment. It is supposed that the cyst, possibly as a result of galvanic treatment, ruptured, and its contents became diffused through the abdomen and caused multiple small peritoneal cysts. The subsequent pigmentation of milk, sweat, and urine is attributed to the traumatic effect or to changed pressure relations following operation and labor, respectively. The structure of the cysts examined and the composition of the pigmented milk, speak against the case being one of delayed fatality in melanosarcoma. The case is reported as a remarkable simulation of the clinical features of melanosarcoma without malignancy.

The Treatment of Erysipelas.—E. Laplace reports experiments made to find whether or not it is possible to alter the virulence of staphylococci and streptococci so as to explain the clinical phenomena. He found that by taking a virulent strain of streptococcus and incubating it in an acid medium, the streptococcus changed to an apparently typical staphylococcus, while the same strain incubated in an alkaline or neutral medium retained streptococcic appearance and virulence. He also refers to his earlier discovery that the acidifying of a bichloride of mercury solution would take away its action of coagulating the blood, thus rendering it more useful as an antiseptic application. Applying these facts to the treatment of erysipelas, he has used acid, ice-cold bichloride of mercury solution locally in the treatment of this disease, making minute scarifications, especially for two or three inches beyond the infected areas so as to lay upon the lymphatic vessels. The venous capillary hemorrhage thus caused allows vast numbers of the infecting cocci to escape, and the ice-cold compress, kept wet with the solution and applied to the lymphatic vessels, helps to destroy those remaining. If the infection is deeper, involving the cellular tissue, an incision should be made over the infected area for thorough drainage and disinfection. If the nose or some delicate part of the face is involved the scarifications may be replaced by copious acupuncture. He has employed this method in a large number of cases, both in hospitals and private work, with unfailing success in checking from the first the starting infection, and he believes that by this local treatment, in conjunction with the constitutional tonic treatment with tincture of chloride of iron, all the indications will be met.

The Lancet, July 6, 1907.

Some of the More Unusual Forms of Acute Conjunctivitis.—An investigation into this subject has been made by A. C. Hudson and P. N. Panton, who report in detail with reference to the streptococci, *Staphylococcus aureus*, an intermediate staphylococcus, an unclassified coccus, *Staphylococcus albus*, gonococcus, diphtheria bacillus, and diphtheroid bacillus. In each instance two or more film preparations were made from the discharge and a culture taken on to some form of solid medium. The films were stained and examined *pro forma*, but diagnosis was not made from the films alone, except in some cases of gonorrheal infection in which attempts at cultivation failed. The author concludes as follows: That both *Staphylococcus albus* and *Staphylococcus aureus*, as well as streptococci, are capable of exciting an acute conjunctival inflammation. That these organisms when they are present as the only pathogenic bacteria in an inflammatory conjunctival discharge should be considered as the causative agents. That these orgamisms give rise to a considerable percentage of all cases of acute conjunctivitis. That the severity of the type of inflammation they produce varies on the whole directly with the generaliy recognized pathogenicity of the members of the group, the most severe cases being associated with the streptococci and the least severe with the white staphylococci; but that the severity of the symptoms produced by any of the individual organisms may vary considerably with the idiosyncrasies of the patient. That there is reason to suppose that these bacteria, when associated with other pathogenic organisms, tend to increase the severity of the conjunctival inflammation. That the types of acute conjunctivitis due to these organisms, although presenting no pathognomonic features, are not infrequently suggestive of their etiology. That staphylococcal, as well as streptococcal, infection of the conjunctiva is liable to be associated with membrane formation. That conjunctivitis due to the diphtheria bacillus is uncommon and may be difficult to diagnose on clinical grounds. That diphtheroid bacilli are present in a high percentage of cases without appearing to influence the nature of the processes. It is probable that they represent more than one species and it is possible that some of these may be pathogenic to man; but there is no evidence that they may ever become transformed into the genuine diphtheria bacillus. That sporadic cases of pneumococcal conjunctivitis must be of rare occurrence (in London not a single case being met with in this series). Inasmuch as the diagnosis of this organism from a streptococcus may be a matter of great difficulty, its identification by film preparations only or by incomplete cultural investigations cannot be relied on; the mere appearance of encapsulation of the organisms in the films is most unreliable as a means of diagnosis. These observations agree with the investigations of others as to the rarity of organisms of the bacillus coli group as causes of acute conjunctivitis.

Separation of the Acetabular Epiphysis of the Femur: Its Relation to Adolescent Coxa Vara.—P. W. Sargent and L. A. Kisch regard separation of the acetabular epiphysis as not uncommon and notes the general recognition of its etiological relation to adolescent coxa vara. They recently presented to the London Medical Society the case of an epileptic boy who had fallen in a fit and showed a condition of recent separation of the right acetabular epiphysis without having any knowledge that there was anything wrong with his joint. The case is described in full with reproduction of skiagraphs. From a study of the latter and of some ten other cases as well as of an equal number of cases of coxa vara, the authors differentiate two classes of this condition: (1) Those cases in which there is only rotation on an horizontal antero-posterior axis, and (2) those in which there is rotation on both an horizontal and on a vertical axis. In the first class the symptoms are slight and there is only slight impairment of mobility. The treatment consists in wrenching under an anesthetic and immobilizing in the abducted position in a suitable apparatus for two or three months and then the use of patten and crutches for a year. The prognosis is excellent and skiagrams taken after this treatment has been carried out show no evidence of abnormality whatever. In the second class the symptoms are more severe, and the author declares that the greater the vertical rotation the severer the pain and immobility. The

pain is due to pressure on the capsule. The treatment is more difficult. An attempt should be made under an anesthetic to wrench the bones into place, but if not successful the neck must be screwed or nailed to the epiphysis, the femur first being rotated and abducted until the fractured surfaces are in apposition. The prognosis is worse than in the first class. If a case of separated epiphysis with a history of injury is untreated the deformity known as traumatic coxa vara results. Now the skiagrams of traumatic coxa vara are exactly similar to those of ordinary adolescent coxa vara, and as in the traumatic cases the injuries are always trivial, the view has gradually developed that these conditions are really one and the same, that is, that all cases of adolescent coxa vara are due to a previous separation of the epiphysis. All cases, therefore, of slight limp or aching about the hip joint in patients between twelve and eighteen years call for immediate skiagraphy, so that the condition of separation may be detected in its incipiency and the case be prevented from passing into the second class above specified.

Intermittent Hydronephrosis Treated by Operation.—Two cases are reported by G. W. Watson Cheyne, whose paper contains several illustrations. Both patients, woman, aged thirty-two, and man, aged twenty, recovered. In both the left kidney was involved. The author considers the condition found in both the most common one found in such cases, at least, such a statement is borne out in his personal experience. This condition is the attachment of the ureter too high up on the pelvis with the result that a valvular opening is formed which tends to become closed when the ureter is distended. He is not prepared to say whether the condition is congenital or acquired. In all the cases he has seen the kidney has been freely movable. As a result of that mobility the ureter may become kinked or curved from time to time, so that there is a difficulty in the urinary outflow. As a result the pelvis becomes distended and as it yields more at the lower part than elsewhere a pouch is formed below the ureteral attachment. Consequently in time the ureter comes to arise from the upper part of the dilated pelvis and thus the orifice tends to become blocked as the pouch fills with urine. As an argument against this theory the author reminds us that the ureter in these cases does not come off straight from the dilated pelvis, but is adherent to the wall of this sac for some little distance, so that one may put one blade of a pair of scissors into the ureter and the other into the pelvis and cut the intervening wall of pelvis and ureter for a little distance without opening the cellular tissue beyond. This looks more like a congenital malformation. The author describes his surgical technique as follows: An oval piece of the pelvis of the kidney containing the orifice of the ureter is excised, the greater extent of the oval being above the ureter. At the lower part the incision runs about a quarter of an inch below the point where the ureter leaves the pelvis, at the sides it is carried out to about half an inch, and at the upper part rather more. This piece being detached the orifice of the ureter is inspected and one blade of a pair of scissors is introduced into the ureter not quite down to the point where the ureter loses connection with the pelvis, and the other blade being on the pelvic surface the scissors are closed and in this way a slit-like opening is made and the valvular orifice is got rid of. The wall of the ureter and that of the pelvis along this cut, and more especially at the lower angle, are now united by three or four fine catgut sutures. A piece of the lower part of the dilated pelvis is now cut away corresponding in size and shape to the above, and the ureter is then fastened into this opening by a series of Lembert catgut sutures. If deemed advisable a portion of the dilated pelvis may now be cut away and the opening stitched up in a linear direction. If possible it is well to avoid any connection between this incision and that in which the ureter is attached, as leakage is apt to occur at the angle of union.

British Medical Journal, July 6, 1907.

Post-Scarlatinal Desquamation.—A child came under the observation of F. J. Vincent Hall with scarlatina presenting a copious rash. Although closely looked for, desquamation of even the most floury nature was never observed. At the end of about five weeks she appeared perfectly well, except for a very slight aural moisture. Two or three weeks afterwards her father developed scarlatina with every other symptom of the disease, except a rash. This no one ever could detect. At the end of six weeks, no desquamation having taken place, and feeling perfectly well, he suggested to the author that he should take a fortnight's holiday, at the expiration of which he considered he might safely resume his practice. A few days later the author received a letter from him stating that he was peeling profusely, and he returned home. It was nearly two months before all the desquamation ceased. Three months after her attack was apparently cured, the little girl was sent to her grandmother's in the country. While out for a walk a nursemaid, accompanied by the child and a small boy cousin, used her own pocket handkerchief to both the boy and the girl. Both the boy and the nursemaid developed scarlatina in a few days, and had it severely. There was at that time no other case in the district. The author states that long ago he came to the conclusion that the desquamation stage of scarlet fever is not infectious, provided the throat is well and there is no nasal nor aural discharge.

Spontaneous Aneurysm of the Dorsalis Pedis Artery.—The patient of A. Cuff, a woman of fifty-three years, had noticed a small swelling on the dorsum of the left foot for over two years. For the few weeks previous to observation by the author it had given no trouble, but recently had begun to enlarge and to give the patient considerable trouble. There was no history of trauma or syphilis. Examination showed on the dorsum of the foot a pulsating, expansile swelling, the size of a small walnut, over which the skin was thinned and slightly reddened. It lay toward the point of termination of the dorsalis pedis artery. The arteries generally were somewhat thickened, vascular tension increased, and the aortic second sound accentuated over the valves. The aneurysm was excised, the resected portion of the artery showing well marked endarteritis with considerable thickening of the vessel walls.

Sterility Among X-Ray Workers.—A. C. Jordan refers to this untoward result of *x*-ray work upon operators. He has not found any data bearing on possible recovery from sterility thus produced. If it is recognized while there are still immobile spermatozoa, it would appear possible that two or three years of complete abstinence from *x*-ray work might result in some degree of recovery. After some remarks on protective devices used by others, he suggests as sufficient the following protective measures: The tube box should be made entirely of wood, and should be completely lined on the outside with an efficient protective rubber material with the exception of an aperture at the top which is controlled by an adjustable diaphragm. A view of the tube may be obtained through a small lead-glass window covered with a flap of a protective material. The operator should always wear a protective apron reaching from the shoulders to below the knees, and, as these two means are not sufficient, he should also have an upright rectangular wooden screen, three feet three inches in height and two feet in width, lined on both faces with three-pound sheet lead, and should place it close to the couch between himself and the tube box. A larger screen (say four feet square) should be supplied for use while *x*-ray treatment is in progress. The screens may be mounted on castors. Screens of the sort described are not in the operator's way to an uncomfortable extent. For treatment the tube should always be completely enclosed. Eventually, the author believes, sheet metal shields and tube boxes will be available, but this cannot well be before static machines have been so far improved and developed as to be used in place of induction coils, as has been done with great success.

The Care of the Patient During Serious Abdominal Operations.—H. B. Gardner refers to certain points which he believes to be of value. Strychnine should be given t. i. d. for a week previous to operation. Strong purgation the night before is to be avoided, as it temporarily lowers the general blood pressure. Rest in bed should be insisted on for two or three days preceding with regulation of the diet and compliance with nursing discipline. The body should be thoroughly clothed during operation. Hot water beds are often advisable in long procedures. Thin blankets are quite inefficient as heat preservatives and all blankets should be heated. Large surfaces of the body near the wound should not be exposed or covered with wet cloths, which produce rapid chilling of the skin by cooling and evaporation, and if these are to be used mackintosh and, if possible, blanket also should lie beneath them. It must not be forgotten in this connection that exposed intestines and other vascular organs produce a rapid loss of heat and should be covered when drawn out by a succession of warm sponges or wads of gauze. A patient always begins to flag when eviscerated bowel is allowed to cool. Syncope due to the removal of the weight of fluid or tumors from the splanchnic area may be anticipated and prevented by the surgeon removing the tension slowly, and the anesthetist lowering the patient's head at the same time. After an operation conducted in either the Trendelenburg or the lithotomy position, if hemorrhage has occurred it is best not to let the patient down flat at its termination, but to keep the feet raised for some hours afterwards to prevent the supervention of cerebral anemia before the blood pressure

has returned to normal level. In deep stages of anesthesia the vasomotor mechanism is paralyzed and whenever shock or hemorrhage begin to appear the anesthesia should be lightened so that the vasomotor system may recover its activity and readjust the disturbed blood pressure.

Berliner klinische Wochenschrift, July 1, 1907.

The Use of Morphine in Asthma.—Goldschmidt says that while all the textbooks contain the strict injunction not to give morphine to asthmatic patients, and the number of morphine habitués who are led to begin the habit through its administration for this disease is very large, nevertheless most practitioners find it necessary to resort to opium in many of their cases of asthma. He himself is of the opinion that if carefully watched and controlled the use of the drug is not very dangerous and forms an almost indispensable part of the treatment. Two broad types of cases may be distinguished, those in which the attacks occur at rare intervals and those in which a more or less persistent asthmatic state or status asthmaticus exists. There can be no objection to giving morphine to patients of the first type who have attacks lasting only one or two days, but even in instances of the chronic form for a time at least it may be used without danger. A point of great importance is to realize what exceedingly minute amounts suffice to produce the desired effect. Doses ranging from three to five milligrams hypodermically are usually competent to bring relief in even the severest attacks. Administered in this way there is little tendency to producing addiction, but when the first symptoms of morphinism, instanced by the demand for a considerable increase in dosage, appear, some more harmless, though less efficient substitute, like chloral, must be employed.

Münchener medizinische Wochenschrift, June 25, 1907.

Phosphaturia in Gonorrhea.—Oppenheim does not agree with those observers who believe that the phosphaturia which so frequently accompanies gonorrhea is the result of a secretory neurosis of the kidney attending a condition of sexual neurasthenia, nor with those who hold that the peripheral disease of the urogenital apparatus exerts a reflex action on the kidney, causing it to secrete phosphatic urine. He expresses the opinion, which he seeks to corroborate by clinical observations, that the phosphates of the urine are precipitated owing to the addition to it of the alkaline secretions of the inflamed urethra and its glandular structures. It is notably the prostatic secretion that has this effect, which is further enhanced through the fact that the usual dietetic régime prescribed for gonorrheal patients involves a reduction in the normal urinary acidity. Owing to this cause even small amounts of alkali are sufficient to induce the precipitation of the urinary phosphates. It is also possible, though not certain, that there is an actual increase in the amount of calcium excreted by gonorrheal patients.

The Results Obtained in Thoracic Operations by Means of the Pneumatic Cabinet.—Kausch says that there are still differences of opinion, first, in regard to the necessity for the pneumatic cabinet in thoracic operations, and secondly, as to which form of procedure—the increased pressure or the negative pressure method—is to be preferred. While he admits that most of the justifiable thoracic operations can be performed without resort to these measures, he considers that they may be regarded as indispensable in order to avoid operative pneumothorax with its attendant dangers of infection in performing extrapleural pneumonotomy, especially if the lung is infected. They are also very desirable, though not essential, in the treatment of empyema. Owing to the greater opportunities for manipulative control and the less complicated nature of the apparatus, he prefers Sauerbruch's cabinet with negative pressure to Brauer's method of increased pressure, in which serious difficulties are likely to be encountered in the management of the anesthesia.

Deutsche medizinische Wochenschrift, June 27, 1907.

Discharge of the Appendix Through the Rectum.—Groedel describes this remarkable case. The patient was a man of sixty-two years who had been under treatment for some years for diabetes, arteriosclerosis, angina pectoris, and cardiac insufficiency with congestion in the lungs, liver, and kidneys. During convalescence from an exacerbation of these conditions he suddenly developed evidences of diffuse peritonitis. Operation seemed inadvisable owing to the patient's general condition, and after twenty-four days of symptomatic treatment the patient died. On the tenth day of the illness about fifteen enteroliths were discharged, and on the sixteenth day the appendix, measuring eight cm. in length, was found in the stools. During the following days quantities of light green pus were mingled with the feces. The author believes that through the pressure of an enterolith at the opening of the appendix a circumscribed patch of gangrene was caused in the cecal wall, accompanied by necrosis of the mesenteriolum, so that the appendix was enabled to drop back into the cecum and so be discharged with the stools. The tendency to gangrene may have been increased by the diabetes from which the patient was suffering. At a partial autopsy the conditions found seemed to justify such a view.

The Secretion of Milk After Castration.—Grünbaum observed a case in which after a double oophorectomy a copious secretion of milk began on the eleventh day and lasted for several weeks. This led him to watch similar patients with this end in view and he reports twenty additional oophorectomies, in fourteen of which the removal of both ovaries was followed by a more or less profuse mammary secretion. This usually began to appear during the third week after operation; in some instances it ceased after a few days or weeks, but in others it had already persisted for several months. In some of the patients the secretion was very abundant, so that even moderate pressure caused the fluid to squirt from the nipple, but in most cases only a few drops could be expressed. The first secretion obtained was usually colostrum-like, milk appearing later. The patients ranged in age from twenty-three to forty-six years, and six of those whose breasts secreted milk were nulliparas. The author suggests that ovarian tissue may exert an inhibitory influence on mammary activity.

French and Italian Journals.

Enuresis in Children.—Arture Cavalieri classifies enuresis of children, according to the cause, into four divisions, excluding all cases resulting from general, spinal, or brain diseases. The condition is essentially a neurosis, and hereditary nervous conditions are often to be found as remote causes. According to some, the cause is a hypoplasia of the central nervous system. The immediate cause is a hyperexcitability of the detrusor vesicæ, with relaxation of the sphincter of the urethra, or a lack of development of the prostate and failure of the bladder orifice to close. The therapeutic measures must depend on the one of these conditions that exists. General hygienic and dietetic measures are appropriate in all conditions. For hyperexcitability of the detrusor, belladonna in increasing doses at night, valerian and warm baths are the best remedies. For deficiency of the sphincter, strychnine and faradization are useful. For reflex enuresis, the removal of the cause is all that is needed. In deficient closure of the bladder, with other deformities, massage and systematic dilatation of the urethra are useful. The most brilliant modern method of treatment is that of Cathelin, the injection of physiological salt solution into the spinal canal, entering the needle in the hiatus sacralis. The effect is supposed to be due to stimulation of the nerve roots.—*Rivista di Clinica Pediatrica*, March, 1907.

Supplementary Venous Circulations of the Anterior Thoracico-Abdominal Wall, Especially in Affections of the Liver.—A. Gilbert and Maurice Villaret state that in the course of hepatic affections the collateral venous circulation may have multiple origins; they may be due to troubles of the intrahepatic portal vein, the inferior vena cava involved in sclerosis of the posterior surface of the liver or compressed by that organ; or may be due to hypertension of the intraabdominal venous circulation from development of ascites. Certain affections seem to be accompanied by particular forms of venous dilatations, which may be of value in diagnosis of these affections. The circulatory current may be in different directions, according as the different regions of the abdomen are involved. The circulatory type due to lesions of the superior vena cava has a current directed from above downward, and the veins of the superficial layer of the upper thorax and epigastrium are affected. The affections of the inferior vena cava by compression are more complex; they are exclusively subumbilical, and the current is from below upward. They are found in cases of peritoneal tuberculosis, limited tumors of the abdomen, and hernias of the walls. Especially they are due to obliteration of the inferior third of the vena cava inferior. Later the vascularization extends to the portal region and becomes mixed. The collateral circulations in hepatic affections are more interesting. When due to compression of the vena cava inferior they are similar to the previous variety. When there is a pure portal origin it results from atrophic cirrhoses unaccompanied by ascites. There are four forms of circulations: by dilatation of the umbilical system of veins; by dilatation of the superumbilical and thoracic veins; by dilatation of veins predominating on the right side along the thorax; by circulations of several varieties. When we have a peri and superumbilical circulation, principally localized over the xiphoid region, or along the thoracic region, whose current is from below upward, we may consider it due to portal lesions.—*Revue de Médecine*, April 10, 1907.

Book Reviews.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles. Edited by A. O. J. Kelly, A.M., M.D., Philadelphia, U. S. A. Volume IV. Sixteenth Series, 1906. Philadelphia: J. B. Lippincott Company, 1906.

This volume of the well-known quarterly contains lectures and articles on therapeutics, medicine, surgery, obstetrics, gynecology, laryngology, and otology. Among them we find a very instructive, plainly written article on electrotherapeutics by Dr. J. H. W. Rhein of Philadelphia, in which the essentials of the subject, as the appeal to the practitioner, are given in a most lucid style. There are also good articles on the treatment of chronic nephritis by J. M. French of California, and on chronic constipation by J. D. Steele of Philadelphia. Brief articles on obesity and on ureteral calculi, by P. Grocco (Florence) and H. Lilienthal (New York), respectively, close the section on treatment. In the section on medicine there are important contributions on tuberculosis by W. Porter (New York), J. E. Squire (London), and Henry Sewall (Denver); on hematuria by A. R. Elliott (Chicago); on myxedema by R. S. Morris (Baltimore); syphilitic aortitis by C. Dieulafoy (Paris), and on diseases of the suprarenals by Léon Bernard (Paris).

In the surgical sections two articles attract attention, that of G. Ross (Philadelphia) on fractures of the lower limbs, and that of Russell A. Hibbs (New York) on hip-joint disease. David Wallace's (Edinburgh) article on vesical tumors is instructive, and presents a comparatively obscure subject most attractively. In G. P. Muller's (Philadelphia) article on hemorrhoids we find nothing on the "office treatment" so popular in this country. He gives an admirable description of the operative technique of operations for piles, preferring the McBurney method, which is well illustrated in his article. The article on placenta prævia by J. B. De Lee (Chicago) is worth reading indeed, as it is probably the best review of the subject published. Practical articles on lacerations of the cervix, by Newman Dorland (Philadelphia), and on cystitis in woman, by D. H. Craig (Boston), on laryngeal tuberculosis, by E. F. Trevelyan (London), and on the mastoid operations, by C. W. Richardson (Washington), close this most valuable volume. The diversity of subjects therein treated is great, and all classes of physicians will find something in it that will suit their needs.

Traitement du Mal de Pott à l'usage des praticiens. Par le Dr. F. Colot, Chirurgien en chef de l'Hôpital Rothschild, de l'Hôpital Cazin-Perrochaud et de l'Institut Orthopédique de Berck. Paris: O. Doin, 1906.

This is a very concise, exceedingly practical little book on the treatment of Pott's disease and its common complications. It is written for the general practitioner, and tells exactly how to make plaster jackets, etc. Colot is a firm believer in the reduction of kyphoses by slow and gradual compression. For this purpose he directs the physician to make an opening in the back of the plaster-of-Paris jacket, large enough to allow the kyphos to project, and then to pack the opening with a half-dozen layers of cotton. These are held in place by adhesive straps. Thus gradual pressure is made on the projection. At intervals the dressing is renewed, the amount of padding being increased up to twelve or eighteen layers. The edges of the cotton squares are pushed in under the edges of the opening in the plaster-of-Paris. Very simple and perfectly intelligible illustrations show how all this is done. A number of photographs of cases show excellent results from this treatment.

Physical Chemistry in the Service of Medicine. Seven Addresses by Dr. Wolfgang Pauli, Privatdocent in Internal Medicine at the University of Vienna. Authorized Translation by Dr. Martin H. Fischer, Professor of Pathology at the Oakland College of Medicine. New York: John Wiley & Sons; London: Chapman & Hall, Limited, 1907.

Physical chemistry has already begun to play so important a part in the fundamental conceptions of modern medicine, and appears to be destined to so brilliant a future in the solution of many of the problems of medical science that the thanks of the profession are due to Dr. Fischer for having made this series of lectures available to those who do not read German. Dr. Pauli's addresses form a simple and easily intelligible introduction into the complicated lore of ions and electrolytic dissociation, sols and gels, catalysis and viscosity, and should prove most acceptable to all who desire to keep pace with the important advances that the masters of the subject are making. The author has made his work doubly interesting to the average reader by pointing out the practical significance of many of the theoretical principles considered, and questions of physiology, pathology, and pharmacology are all dwelt upon. Sections of particular practical interest are those in which the applications of colloidal chemistry to the doctrine of the toxins and antitoxins, and of the therapeutic possibilities of the sulphocyanates are discussed. The little volume contains a wealth of information on subjects of the greatest import in the development of our art, and should prove a boon to those who are anxious to be well informed, but have not the opportunity of pursuing extensive studies in so very intricate subjects. The translation is an excellent one, and Dr. Fischer has succeeded admirably in paraphrasing the difficult terminology of the original into appropriate English terms.

Green's Encyclopedia and Dictionary of Medicine and Surgery. Vol. III. Earth Burial to Gummi Indicum. Edinburgh and London: William Green & Sons, 1907.

In the third volume of this excellent work there are 1,097 titles of which 60 are of more or less important articles. Among these we may mention Eclampsia, Ectopic Gestation, Eczema, Electricity, Enteroptosis, Erysipelas, Eye, Facial Paralysis, Foot, Fractures, Gall-bladder Diseases, Gangrene, Gastrointestinal Disorders of Infancy, General Paralysis, Female Organs of Generation, Glaucoma, Glycosuria, Gonorrhea, and Gout. Of articles from 80 to 900 words in length there are over one hundred, and of shorter articles, pactically simple definitions or cross references, there are over 900. The volume is illustrated wherever necessary, but it is not at all profusely illustrated, the pictures being introduced evidently only to elucidate the text, and not for the sake of making a show. As a work of ready reference, combining the dictionary and encyclopedic features, this leaves little to be desired.

The Practical Medicine Series, Comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Under the General Editorial Charge of Gustavus P. Head, M.D., Professor of Laryngology and Rhinology, Chicago. Volume VIII. Materia Medica and Therapeutics, Preventive Medicine, Climatology, Forensic Medicine. Edited by George F. Butler, Ph.G., M.D., Henry B. Favill, A.B., M.D., Norman Bridge, A.M., M.D., Daniel R. Brower, A.M., M.D., LL.D., and Harold N. Moyer, M.D. Series 1906. Chicago: Year Book Publishers, 1906.

This eighth volume of the popular series of annuals covers five different departments of medical science in a duodecimo of 358 pages. It cannot be expected that an exhaustive analysis of the year's progress in all these branches can be given in such a limited space. The subjects are therefore handled very briefly, but sufficiently for the purposes for which these annuals are got up. In the chapters on materia medica are to be found brief notes on the new remedies of 1905, some of which have become more or less generally used. Under the heading of preventive medicine much attention is paid to the sanatorium treatment of tuberculosis.

Practical Gynecology: A Comprehensive Textbook for Students and Physicians. By E. E. Montgomery, M.D., LL.D., Professor of Gynecology, Jefferson Medical College; Gynecologist to the Jefferson Medical College and St. Joseph's Hospitals; Consulting Gynecologist to the Philadelphia Lying-in Charity and the Kensington Hospital for Women. Third Revised Edition. Philadelphia: P. Blakiston's Son & Co., 1907.

The general plan of this edition is the same as that of the former two, the changes being chiefly in the nature of additions to keep pace with the advance in this branch of surgery. The section on etiology is new and so is the subject of blood examination. For some curious reason the latter is included in the section on Animal Parasites, and this in turn is placed in the chapter on Pelvic Examination—at least the running page heads would so indicate. Exploration of the Urethra, Bladder, and Ureters is another subject included in the section on Animal Parasites. The sections on Microscopic Diagnosis, Gynecic Bacteriology, and the Pathology of Carcinoma Uteri have been extensively revised. A number of illustrations have been added. The pictures are a very praiseworthy feature of the book; most of them are original, many are beautifully executed, and all are useful. Dr. Montgomery's Gynecology is a deservedly popular work and it will remain so as long as the successive editions are so carefully and conscientiously revised as is this one.

Notions Élémentaires de Prophylaxie des Maladies Tropicales. Par R. Wurtz, Professor agrégé chargé de cours à l'Institut de Médecine Coloniale de Paris. Paris: Vigot Frères, 1906.

This pamphlet of thirty pages is a useful contribution to the study of the hygiene of tropical countries. Both physicians and laymen would derive benefit from a perusal of its pages.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Fifty-eighth Annual Session, Held at Atlantic City, June 3, 4, 5, 6, and 7, 1907.

Special Report to the MEDICAL RECORD.

(Continued from page 81.)

SECTION ON DISEASES OF CHILDREN.

Thursday, June 6—Third Day.

The Opsonic Index in the Tuberculosis of Children; Its Relation to the Tuberculin Test.—Dr. THOMAS MORGAN ROTCH of Boston, Mass., read this paper, in which he emphasized the growing demand for making an early diagnosis in tuberculosis, particularly in children. It was an established fact that early diagnosis meant cure. The two means for making an early diagnosis were the tuberculin test and the opsonic index. The former should be used only by trained observers and with the greatest care. A positive reaction had been obtained in 99 per cent. of cases of tuberculosis, but a negative result did not necessarily exclude the presence of tuberculosis. In his experience the giving of an overdose of tuberculin had proved serious. Children, however, took it without danger if given in the proper way. Interrupted doses were not necessary. He advocated giving the reaction dose. In one case the question had arisen as to whether the tuberculin was curative. The opsonic index had been taken in some cases in children to determine whether tuberculin had better be given as a test; and also, if tuberculosis were present, whether a large or small dose of tuberculin should be given in connection with the treatment. The general rule in giving the vaccine was that the initial injection should be very small. When small increasing doses had been used over a long time reactions had been very few, therefore he had been encouraged to continue studies along this line. He suggested that in the future the different vaccines would probably be used for diagnostic purposes, though he did not wish to go on record at present as advocating their use for this purpose.

Dr. CHARLES GILMORE KERLEY of New York City said the observations at the Babies' Hospital, under Dr. Holt's service, coincided with the experience of Dr. Rotch, and that no harm had come from the use of tuberculin; also that one injection sufficed. A useful field for this test was in tuberculous peritonitis, where the diagnosis was often very difficult.

Dr. ISAAC A. ABT of Chicago, Ill., warned against being too reckless with the use of tuberculin. He had had some sad experiences with it. Not more than two milligrams should be used at a dose.

Dr. LOUIS C. AGER of Brooklyn, N. Y., had found, in following the literature of the subject, that there is a wide divergence of opinion as to what constitutes the safe dose. This should be more accurately determined. He asked if Dr. Rotch had confined his experiments to the old tuberculin.

Dr. A. W. FAIRBANKS of Boston, Mass., said the impression against tuberculin was due to the teaching of Virchow and his pupils, who believed tuberculosis in many cases was disseminated by its use. His own prejudice against it was being gradually overcome.

Dr. RUSSELL S. ROWLAND of Detroit, Mich., cited a case of tuberculous peritonitis in which the patient was in too bad a condition to warrant operation. Tuberculin was given as a last resort, and rapid improvement followed, the fluid disappearing rapidly. Operation in this case now thought to be unnecessary. He cited a post-operative case which was improved under the opsonic treatment. Two facts had been brought out by this treatment, viz.; First, that in tuberculous peritonitis the index was low before treatment; second, that when the index is raised the patient is put in better condition for operation. After operation the opsonic index went down and remained down for a long time, which showed that the operation might be an autogenous method of producing vaccine which gradually improves the condition. He mentioned a case of meningitis of the diplococcus type, which he had seen late in the course of the disease. He made a vaccine, but the parents of the patient would not consent to its use. The child recovered. If he had used the vaccine the recovery would have been attributed to its effect.

Dr. ROTCH, in closing the discussion, said he had used only the old original preparation. So far as he knew there was no difference in the efficacy of the old and the new preparations, but with the latter small doses must be given. At the Infants' Hospital, as well as at the Massachusetts General Hospital, it had been routine practise to test for tuberculosis with tuberculin. Given properly, it was no more dangerous than opium, strychnin, or any other remedy. The dose for children was two to five milligrams; as much as ten milligrams had been given. One milligram would very seldom give the reaction. It might be given in interrupted doses when a slight reaction is desired. Two milligrams was a diagnostic dose. For therapeutic purposes small doses were given.

Tardy Malnutrition; Its Treatment by Rest and Diet.—Dr. CHARLES GILMORE KERLEY of New York City presented this communication. He referred to children who, after two years, while free from diseases such as tuberculosis, syphilis, chronic nephritis, etc., showed marked developmental defects in that they were underweight and undersized. They might be of average height, but were always of under-weight; they tired easily; had diminished resistance to exercise as well as to disease; suffered invariably from anemia, and had no appetite. Simple digestive disturbances in such children would require several days before relief could be accomplished. They were found in all classes of society. Careful study of each case would invariably demonstrate that the patient was not getting what a growing child has a right to expect. One fact in child management was often lost sight of by both layman and physician, viz.—that the child has a definite business to perform—growth and development into physically the best type of adult. All other interests should be subservient to this. The acquirement of knowledge, for example, should never stand in the way of physical development. The chief cause of malnutrition in older children as in infants, was defective nutrition, due to ignorance of food values. The next important factor was excessive expenditure of energy and inadequate rest. Here various influences were operative. In order to attain the best physical development the child, up to the eighth year, should sleep twelve hours out of the twenty-four. Late hours, entertainments, children's parties, boxed breakfast foods, etc., were to be deprecated and deserved part of the blame which had attached to long school hours and overwork at school. Heredity was a factor; but he had found that when these children were put on a rational method of living improvement in weight followed. He outlined his scheme of management in such cases, which consisted in the proper selection of foods and the regulation of the environment and habits of life, in order that the food might be best utilized.

Dr. THOMAS MORAN ROTCH of Boston, Mass., believed that the usual treatment with drugs in these cases had had its day.

Dr. J. W. VAN DERSLICE of Oak Park, Ill., agreed with Dr. Kerley that the regulation of the diet and the insistence upon adequate rest were the important points in the management of such cases.

Dr. JOHN LOVETT MORSE of Boston, Mass., subscribed to all Dr. Kerley had said. Intellectual development was of no consequence compared with physical development.

The discussion was continued by Dr. STOWELL of New

York City, Dr. McKee of Philadelphia, and others, and closed by Dr. Kerley.

The Percussion of the Chest in Infants and Children. Dr. S. McC. Hamill of Philadelphia, Pa., called attention in this paper to the fact that the tendency to-day is to neglect percussion of the chest in early life, and protested against the neglect of so valuable a procedure. He detailed the methods for percussion of the lungs and heart, the best position for each, and the external influences which affect the result. He particularly emphasized the importance of minimizing the percussion stroke.

Dr. Arthur Willard Fairbanks of Boston, Mass., advocated the use of the stethoscope in connection with very light percussion.

The paper was further discussed by Dr. Lowenburg of Philadelphia, Dr. McKee of Philadelphia, Dr. Hand of Philadelphia, and others, and the discussion closed by Dr. Hamill.

Symptom-Complex of a Series of Intestinal Cases in Children with Pathological Findings.—Dr. Thomas D. Parke of Birmingham, Ala., detailed, in this paper, a series of eighteen cases which had come under his observation between the months of May and October during the years 1904, 1905 and 1906, description of which he had not been able to find in the literature. The chief symptoms which characterized the cases were rapid abdominal breathing, air hunger, rapid pulse, cessation of bowel movements, respiratory moan, engorgement of the liver, and, as a rule, lowered temperature. The attack was preceded by stools containing blood or blood and mucus for a few days. Within twelve hours of the onset of the attack the liver, not palpable below the margin of the ribs, could be distinctly felt, and in forty hours it could be felt four inches below. The urine was normal in quantity in all but one case; albumin was found in some cases. Jaundice was absent in all cases. Leucocyte count in one case showed 25,000, mostly polynuclears. All but one case showed prolonged convalescence, loose stools, and tardy restoration of the digestive function. Of the eighteen patients twelve died, six recovered. Fourteen were males and four females; the youngest was six months and the oldest twenty months, and all were breast-fed, previously healthy children. The cases occurred in different parts of the city and in good surroundings. In eight cases autopsy was allowed. The findings were negative except as to the mucosa of the intestine and in the liver. The liver was enlarged to a greater or less extent in all cases and showed fatty degeneration. The gall bladder in every case contained dark green, ropy bile, as did the intestine. Unsuccessful attempts had been made to work up the bacteriology of the cases. The etiological factor had not been determined, but it would seem that a toxin had been generated in the intestinal tract that caused the fatty degeneration of the liver. How the air hunger was caused was a matter of speculation. The treatment had been eliminative. Food was withdrawn and the patient kept on water until food seemed to be needed.

Dr. Isaac A. Abt of Chicago, Ill., called attention to the fact that two years ago he had reported two cases with this symptom-complex before this Section, and had asked the members if they had seen similar cases; they had not. The cases were followed to autopsy and showed very extensive fatty degeneration, so extensive, in fact, that the pathologist reported that it looked like phosphorus poisoning or acute yellow atrophy. In both cases there was, toward the end, mechanical obstruction of the bowel. Both became tympanitic, and could pass neither flatus nor feces. In one of the cases, where some of the urine taken from the bladder was examined, not only albumin and casts were found, but leucin and tyrosin, indicating a destructive process. He did not know the etiology of the disease. He had been told that it was what had been known in newly settled communities as "milk sickness."

Dr. Annie L. Sawyer of Atlanta, Ga., asked if Dr. Parke had noticed in any of the cases reported gingivitis or dark, tarry stools.

Dr. John Lovett Morse of Boston, Mass., said this symptom-complex was characteristic of acid intoxication with acetone bodies. In several cases he had found these acetone bodies in the urine. This was not of much importance, however, as anybody that had been vomiting and taking no food would show these bodies. He had treated such cases with bicarbonate of soda with resultant improvement, but not cure.

Dr. Charles Gilmore Kerley of New York City did not think these cases particularly unusual. The enlargement of the liver was not unusual, nor was it of very great significance, the degree depending upon the length of time during which the organism had been subject to the toxemia. He considered the condition due to some peculiar form of toxemia. The difficult respiration was doubtless due to some toxin which affected the respiratory system.

Dr. A. H. Wentworth of Boston, Mass., said these resembled experimental cases. The mere presence of fat in the liver did not show that the liver was degenerating.

Dr. Parke, in closing the discussion, said that all who had examined the microscopic sections had agreed that there was true fatty degeneration of the liver. As to mechanical obstruction of the bowel, this had not been found in his cases. He cited one case in which the physician in charge had told him that there was peritonitis and obstruction of the bowel; at autopsy neither was found. There was no affection of the mouth in any case. The stools were dark green in every instance. The pulse and respiration ratio varied. As a rule the respiration varied from 50 to 75 and the pulse from 130 to 167.

Five Hundred Cases of Whooping-Cough Treated by Means of the Abdominal Belt.—Dr. Theron Wendell Kilmer of New York City said, in this paper, that of the 500 cases in his own practice and in that of other physicians with whom he had been in correspondence, 93 per cent. had showed marked improvement from the use of the abdominal belt, the improvement being particularly marked with reference to the vomiting. Patients who had worn the belt from the outset had usually been free from complications. Gain in weight had been noticed during the disease. He gave a description and presented cuts of the latest improved abdominal belt, and outlined the method of its application.

Dr. Charles Gilmore Kerley of New York City thought the belt would help the child to come out of the attack better because it would enable him to keep down his food. With reference to the vomiting, the belt was of great benefit. It was particularly useful with little babies. He had never seen a case of hernia from it.

Dr. Louis Fischer of New York City reported improvement in fully 70 per cent. of the cases in which he had used the belt. He had never seen a case of hernia caused by it. He reported one case of epistaxis and prolapse of the rectum which was benefited in two hours after the belt was put on.

Dr. Kilmer, in closing the discussion, said that hernia is more frequent in cases where the belt is not used than in when it is. He agreed with Dr. Kerley that it is particularly useful in young infants to whom medicine cannot be given.

Scarlatina and Duke's Disease.—Dr. A. C. Cotton of Chicago, Ill., presented this paper, in which he reviewed the recent epidemic of exanthemata in Chicago, and gave an analytical study thereof with reference to diagnosis. Opinions *pro* and *con* concerning the probable existence of a fourth exanthematous disease were noted. From this study the questions arose as to whether there are no pathognomonic signs or symptoms of scarlet fever, and whether the conception of the "symptom-complex" of scarlatina must be revised.

Dr. J. W. Van Derslice of Oak Park, Ill., was not sure that all the cases in the recent epidemic referred to which were diagnosed as Duke's disease were so. Whether it was an atypical epidemic he did not know, but he admitted that there were cases which it was possible to diagnose as Duke's disease.

Dr. Louis C. Ager of Brooklyn, N. Y., recalled an epidemic of typhoid fever in which many children were affected, and in which some of the cases presented symptoms similar to those described in certain of the cases mentioned by Dr. Cotton. He attributed them to intestinal toxemia of some kind.

Dr. Cotton, in closing the discussion, said the health department of Chicago had sent out letters to seven hundred physicians asking for information as to the possibility of a new disease. The majority believed that there was no evidence to support the belief in a fourth disease.

Malformations of the Rectum and Imperforate Anus.—Dr. Samuel W. Kelley of Cleveland, Ohio, detailed, in this paper, a description of two cases of severe malformation of the rectum, in neither of which was there an anus. The first presented a minute fistulous opening near the penoscrotal junction. Otherwise appearances were similar—great abdominal distension, with venous stasis. The second case was also jaundiced and feeble. In both cases a search for the rectum was made by the perineal route and none found in the pelvis. In both an artificial anus was made in the left inguinal region, with temporary relief to the patient. Both patients died of exhaustion thirty-two and fifteen hours, respectively, after operation. Autopsy on the first case showed the colon ending in the right inguinal region. The fact was emphasized that it is impossible to predict before operation the location of the enteron. The choice of procedure was outlined.

Dr. E. H. Small of Pittsburg, Pa., Dr. L. T. Royster of Norfolk, Va., and others discussed the paper, and Dr. Kelley closed the discussion.

Clinical Observations in the Acute Infectious Diseases, with Bedside Notes from the Willard Parker Hospital; Practical Deductions with Therapeutic Suggestions.—Dr. Louis Fischer of New York limited the discussion of this subject to diphtheria and scarlet fever, citing in his paper illustrative cases of each disease. During the subnormal condition following various infections, complications easily arose. Rest and extreme caution with the diet were necessary during the convalescent period. The most likely complications that follow scarlet fever, such as otitis, nephritis, or endocarditis, must always be guarded against. The best method for accomplishing this was detailed. Similar considerations applied to diphtheria.

Dr. Arthur Willard Fairbanks of Boston, Mass., thought the rest cure for these cases should be applied also in measles and other acute exanthemata.

Dr. L. T. Royster of Norfolk, Va., said that when he was interne at Willard Parker Hospital nephritis was very common in these cases. Milk was excluded from the diet in order to control this. He asked Dr. Fischer if the same applies in his experience.

Dr. Theron Wendell Kilmer of New York City thought it best to keep these children in bed. The urine should be examined, whether the temperature was normal or not, and it was very important to keep the gastrointestinal tract clear. He asked Dr. Fischer whether diphtheria antitoxin made any difference in his scarlet fever cases.

Dr. H. Lowenburg of Philadelphia, Pa., asked whether Dr. Fischer had followed these cases for three or four years with reference to the kidneys. He recalled cases of scarlet fever in which there had been nephritis, and every time these individuals became ill they developed sore throat, and albumin was found in the urine. The treatment for scarlet fever was the treatment for all the acute exanthemata, and if, in treating these cases, the physician would look forward three or four weeks to the time for otitis media and other complications to arise, he would do most for his patient.

Dr. Fischer, in closing the discussion, said that milk, *per se*, would not cause nephritis to appear or disappear. He had not given diphtheria antitoxin in scarlet fever. By giving protective doses of antitoxin diphtheria had been cut down one-quarter, and this applied to diphtheria complicating scarlet fever. He did not believe that one thousand units would have anything to do with nephritis. He had not watched these cases, as suggested by Dr. Lowenburg, with special reference to the recurrence of nephritis, but it was well known that where it had appeared there was a tendency to recurrence. The vulnerability of the kidneys depended upon the severity of the nephritis.

Differential Diagnosis Between Measles and Rötheln.—Dr. H. M. McClanahan of Omaha, Neb., read this paper, in which he gave a brief history of measles. He had made notes on twenty-seven cases of rubella occurring in an epidemic of this disease. At the same time there was an epidemic of measles and he had consequently been able to study the two conditions by contrast. He believed a distinction should be made between rubella and measles. He called attention to the importance of the prodromal symptoms in measles, particularly of Koplik's spots, to the coryza and lachrymation, the character of the cough, and the temperature, with its wide fluctuations. In contrast to this he pointed out the slight prodromes of German measles, the slight fever and the tender cervical glands. The character of the eruption in each disease, the complications, and sequelæ were detailed and contrasted.

The paper was discussed by Dr. Clarence A. Earle of Des Plaines, Ill., and others, and the discussion closed by Dr. McClanahan.

An Interesting Case of Incontinence of Feces in an Undersized Boy of Six Years.—Dr Maurice Ostheimer of Philadelphia, Pa., reported this case, in which the treatment consisted in the correction of errors in diet and the administration of strychnine gr. 1/60 three times a day, during a period of several weeks. The only recurrence of the incontinence was on the day following that on which the treatment was begun.

Dr. Arthur Willard Fairbanks of Boston, Mass., said these cases occur, as did Dr. Ostheimer's, in defective children, and signified a lack of cerebral control.

Dr. H. Lowenburg of Philadelphia, Pa., agreed with Dr. Fairbanks. He cited two cases, one following cerebrospinal meningitis and the other following typhoid fever of the meningeal type, in each of which the incontinence of feces was controlled by offering the patients rewards.

Essential Insufficiency of the Heart in Childhood.—Dr. Arthur Willard Fairbanks of Boston, Mass., read this paper. Muscular deficiency of the heart was comparable to muscular deficiency elsewhere. Heart development should correspond to the demands made on it by the growing body. Its continued failure to answer such demands constituted a relative insufficiency. This was a frequent condition in childhood. Its causes, the results of such inefficiency on the development of the child, were discussed. Such results were comparable to similar effects seen in valvular lesions, either congenital or acquired early in life.

The Diagnosis and Treatment of Convulsions in Children.—Dr. H. Lowenburg of Philadelphia, Pa., presented this contribution. Convulsions were not to be regarded as a disease entity, but as a symptom. A careful study of the etiological factors was essential to a correct diagnosis and successful treatment. The causes might be grouped as predisposing and exciting. The latter were local, reflex, or toxic. The rôle played by dentition was discussed, as was also the influence of heredity. The diagnosis should be made by process of elimination. The treatment should be rational. Under this head he discussed anesthetics, emetics, purgatives, hydrotherapy, stomach

washing, colonic irrigation, hypnotics, gum lancing, and the treatment between the attacks.

The paper was discussed by Dr. GRAHAM of Philadelphia, Dr. ABT of Chicago and others, and the discussion closed by Dr. LOWENBURG.

MEDICAL SOCIETY OF THE STATE OF NEW JERSEY.

One Hundred and Forty-first Annual Meeting, Held at Long Branch, June 25, 26, and 27, 1907.

(Special Report to the MEDICAL RECORD.)

(*Continued from page* 119.)

Wednesday, June 26—Second Day.

Premature Separation of the Placenta.—Dr. J. WATSON MARTINDALE of Camden read this paper. The object of this paper was to bring before the Society a condition which was very grave and one which required for its management a stout heart and prompt action on the part of the attendant. On July 8, 1906, he was called to see a woman who was seven months pregnant and who had lost consciousness. On examination a small quantity of serous fluid was noted on her underclothing, and the cervix was dilated as large as a dollar and was quite soft. There was no evidence of a placenta coming first, but through the membranes the head could be felt engaging at the brim. There had been no labor pains. The uterus reached to the ensiform cartilage and had a doughy feel. After the examination the patient became unconscious again and he felt suspicious of a separation of the placenta, the blood working its way between the uterus and the bag of waters. He decided to empty the uterus and a dead child was delivered without difficulty. As the child passed the introitus, the placenta was swept out with a tremendous gush of blood, showing that there had been a complete separation of that structure. The uterus contracted well and she did not lose much blood after delivery. Salt solution, injections of whiskey, strychnine, camphor oil, digitalis, and external heat failed to cause the patient to rally, and she died an hour after his arrival. Upon examination of the placenta there was found a large area of calcareous degeneration, and this had been the cause of the placental separation. After quoting cases that had appeared in the practice of other men, he said that the cause of this condition had been attributed to hemorrhagic diathesis, nephritis, hydramnios, short funis, fatty and calcareous degeneration of the placenta. Among the symptoms noted were steady pain in the lower abdomen, weak fetal heart sounds, irregularity of the uterine contractions, with a show of blood. In one-fourth of the cases the hemorrhage was generally concealed until it reached serious proportions. The diagnosis should be made from colic by the absence of shock, and the history of eating some undigestible food, and the presence of constipation. The diagnosis was made from ruptured tubal abscess, by the previous history of tubal disease and localized tenderness over the tubes; from rupture of the uterus because of its more sudden onset, with a gradual diminution in the size of the tumor. The prognosis was bad. The children, as a rule, perished and only the most vigorous women were likely to survive. Cases in which there were no labor pains generally died; some died of shock. If the patient was in collapse, the uterus distended but inactive, with the os rigid, the outlook was highly unfavorable. In considering the treatment, the question resolved itself into Shall we wait, or shall we empty the uterus at once? Some recommended the use of ergot, with firm pressure over the fundus uteri. Brunton said it was best to preserve the membranes and wait for dilatation. Robert Lee said to rupture the membranes, give ergot and stimulants, and use a binder. Fry said if the os was dilated, use forceps or craniotomy; if not, the best was the Porro operation. Murray recommended elevation and bandaging the extremities, stimulants, and the use of the tampon. Coe said, if the head was down, apply forceps; if not, use manual dilatation of the cervix and do a craniotomy or version. Goodell recommended prompt interference; he suggested the application of the forceps, craniotomy, or version. Of 93 cases, 43 were treated on the expectant plan, with 32 deaths; 50 by emptying the uterus, with 15 deaths.

Dr. HENRY H. SHERK of Camden, who had been called in to assist Dr. Martindale in the care of the case just reported, said that nothing was more appalling than a case of this kind, and he related what he did to assist.

Dr. CHARLES P. NOBLE of Philadelphia said that although he was no longer a practising obstetrician, yet he began his active medical career as one, and served five years in a maternity hospital. That experience, of course, was of value to him as a gynecologist. Everyone who attended labor cases should post himself on this question. Although these cases were rare, when they did occur the only salvation for the women was that the man in charge should act promptly and correctly; otherwise the women would invariably die. To-day it was the consensus of opinion of all men who were entitled to have an opinion on the subject, that if a diagnosis of concealed hemorrhage was made, and if the cervix was soft and dilatable, the application of the forceps should be instituted. Otherwise a cesarean section should be performed, providing any one was available who was competent to do it.

Symposium on Diseases of the Gall-Bladder.—The balance of the morning's session was devoted to this interesting symposium.

Etiology and Pathology of Diseases of the Gall-Bladder.—Dr. H. G. NERTON of Trenton said that cholecystitis was nearly as frequent as appendicitis, more difficult to diagnose, and less amenable to treatment than other surgical diseases. It was a very important subject. Cholecystitis was most frequently caused, it was thought, (1) by microbic infection; (2) possibly by toxins, and (3) by direct traumatism to the gall-bladder. In the first group were septicemia, pyemia, influenza, pneumonia, and typhoid fever. The second arose from disease of the alimentary canal, including typhoid fever and dysentery. Appendicitis was sometimes a focus for the spread of infection to the liver and gall-bladder. It might be by direct extension from the duodenum, through the common and cystic ducts, or by the blood-vessels, or by both simultaneously. In general blood infection, the microorganisms might be excreted into the bile ducts or gall-bladder from the hepatic artery and portal vein. That cholecystitis did arise from typhoid infection was proved by the finding of typhoid and colon bacilli in the gall-bladder. Probably slight cholecystitis frequently occurred in typhoid, but was masked by the graver condition, and unless jaundice occurred was usually overlooked. Cholecystitis caused by typhoid infection was said to occur years after the infection; this was proved by the presence of typhoid bacilli. Cholecystitis was usually present at this time; possibly the presence of gallstones and irritation induced by them might be necessary to cause a cholecystitis from the invasion of the gall-bladder with typhoid bacilli. Typhoid bacilli in the blood could not pass through normal hepatic tissue; it probably required that the hepatic tissue and walls of the portal veins should be damaged by the toxins incident to an attack of typhoid or other disease before they could infect the bile duct or gall-bladder. He once saw a very severe acute cholecystitis with jaundice follow an operation for a fulminating appendicitis in a child. This case came near ending fatally, after the onset of the jaundice. There was no evidence of coexisting cholecystitis. The presence of gallstones in cases of appendicitis was, he thought, usually an accidental coincidence. The attack of cholecystitis causing the gallstones, surely long preceded the latest attack of appendicitis with appendical disease. He had never seen a well

marked case of typhoid cholecystitis, but it did occur as a complication. The irritation of previous cholelithiasis might be the factor needed to produce cholecystitis as a complication of typhoid, acting either by obstructing the duct and causing distention, or by ulceration of the mucous membrane from pressure offering an avenue of infection. In cholecystitis the presence of typhoid and colon bacilli, streptococci, staphylococci, and pneumococci, seemed to indicate that any of these microorganisms could cause infection of the gall-bladder. It had been stated that typhoid infection had occurred eighteen years after the attack of typhoid fever. More than one variety of germ had been found at the same time in the viscus. It might be taken for granted that if they had a distended gall-bladder infected by germs of any kind, cholecystitis would follow. Suppurative cholecystitis was due to a further development of the causes of acute, viz., infected calculi, microbe infection. Cancer of the gall-bladder, either primary or as an extension from the liver, was of considerable importance and fairly frequent among visceral forms of cancer. The presence of gallstones in the gall-bladder was probably a frequent causative factor of cancer, but gallstones were frequently present for years in cases in which no cancer developed. In his histories of gallstones he found seven cases of long standing in which no cancer had developed. Primary cancer did occur without the presence of gallstones in about 20 per cent. of the cases. He asked if irritation of gallstones in the gall-bladder of one predisposed to cancer, *i.e.* having a cancerous family history, might not cause cancer of the liver, which had it not occurred in this way might have developed elsewhere? He had treated a case of cancer of the gall-bladder and liver in a man aged fifty, whose mother died of cancer of the womb. Analogous to irritation of gall-bladder as a factor in causing cancer was the greater frequency of uterine and mammary cancer in multiparæ. The gall-bladder was enlarged, or sometimes in old recurrent cases shriveled and contracted, often adherent to parts around it, with the wall of the gall-bladder swollen, softened, and often there was ulceration near the fundus, due to irritation of calculi. The mucous membrane lining of the cystic duct was sometimes so swollen as to be closed.

Diagnosis of Diseases of the Gall-Bladder.—Dr. PHILANDER A. HARRIS of Paterson said that it was the duty of every physician to study carefully any pain that was complained of by the patient. Much could be learned by inspection, palpation, and percussion in diagnosing diseases of the gall-bladder, especially when to this was added the knowledge gained from the clinical history. An abdominal incision often gave such knowledge, that otherwise could not be obtained. The thorax, the abdomen, and the cranial cavities were more or less invaded by the knife of the surgeon, and facts were secured that substantiated or disproved former opinions. After referring to autopsies *in vivo*, he said this was the standstill era in gall-bladder pathology. A stone arrested in the common duct dammed back the bile stream, causing first pain and then colic. It was a physical impossibility to overdistend the gall-bladder, so long as the bile flowed into the intestine without obstruction. The commonest diagnostic symptom was colic. A colic lasting one-half, one, or several hours, with the plain disappearing as quickly as it came on, appearing again after days, weeks, or months, should make one think of gallstones. The pain caused by gallstones was situated usually over the gall-bladder, but sometimes it was situated in the median line in the epigastric region. Pain, again, might be referred to a point between the ensiform cartilage and the umbilicus. This was its location in a considerable number of cases. Ninety per cent. of the so-called cases of neuralgias of the stomach proved to be gall-bladder trouble. The remaining 10 per cent. would be of duodenal, appendical, or stomach origin. When called upon to interpret the meaning of pain in the upper abdomen, lesions of the gall-bladder, cancer, or ulcer of the stomach or duodenum, appendicitis, tuberculosis of the kidney and enteritis should be thought of particularly. Gallstone colic was apt to occur at night and averaged one-half an hour in duration. In the moderately severe colics the patients were apt to assume a variety of postures, but with the body more or less flexed. Occasionally they were found on the floor in the knee-chest position. During this colic the pain usually radiated to the right or left shoulder blades. A large area of the abdomen might be painful. The interval between these attacks might be one week, or even years. Pain after eating, if attended with vomiting, was usually suggestive of gastric ulcer. In some instances blood would be found in the vomit. The colics of gallstone disease were never so frequent as the pains due to gastric or duodenal ulcer. Gallstone colic never bore so close a relation to what was ingested as did cancer and ulcer of the stomach. Cancer of the stomach was usually well advanced before pain and indigestion were complained of. Cancer seldom produced great pain. In real colic the pain radiated outwards, as a rule, and was attended with alterations in the urine. There was pain and tenderness even after the subsidence of the colic, and it might last for hours to several days, and might be so severe as to require the use of an opiate for its relief. If after the disappearance of the gallstone colic pressure be made over the gall-bladder, tenderness at that point would often result. The degree of tenderness on pressure and its duration were not in proportion to the amount of pathology present. The steady pain or tenderness following colic was an aid in diagnosing gallstone disease. With regard to the jaundice, so long as the inflammation and pathology were limited to the gall-bladder jaundice would not appear. In from one-half to three-quarters of the cases in which jaundice appeared it was shown that the pathology had extended below the gall-bladder. When the choledochus was blocked and the bile stream arrested, jaundice resulted. The absence of jaundice should never disprove a diagnosis of gallstone disease. In a large series of cases referred to, jaundice only occurred in 20 per cent. of them. The finding or the not finding of gallstones in the stools was only of restricted value. The screening of the stools was interesting and the knowledge gained might be of some value, but just how much value was obtained from this he did not know. If stones were found in the feces, it gave no knowledge of how many were in the gall-bladder. The appearance of jaundice without colic or pain should not be taken as indicating gallstone disease without a very careful look into the history and symptoms. There were many pathological conditions causing jaundice. The occurrence of jaundice with little or no pain, and with the development of ascites, pointed to a sclerotic condition rather than to gallstone disease. Tenderness in the gall-bladder region was an important symptom in gallstone disease.

Complications in Disease Conditions of the Biliary Passages.—Dr. G. K. DICKINSON of Jersey City read this paper (see page 137.)

Medical Treatment of Diseases of the Gall-Bladder.—Dr. JOHN H. MUSSER of Philadelphia said that this was not a subject of broad lines, yet very much could be said about this condition; not so much about the medical treatment of gallstones, but rather the medical treatment of that state of the liver and the ducts, including the gall-bladder, which offered a tendency for the formation of gall stones—that was, cholelithiasis. Moreover, notwithstanding the fact that it was well appreciated that gallstones were present and that they were doing mischief, in many instances it was appreciated that operative treatment could not be resorted to. This meant that medicinal lines of treatment must be instituted. The age of the person, intercurrent disease, or other circumstances rendered operative procedure inadmissible. Yet for these classes of cases a great deal could be done medicinally. Cholelithiasis, on account of which there was usually a congestion, or in

which there was a congestion and catarrh of the biliary passages and stagnation, with secondary formation of gallstones, had for its origin either toxin influences or influences from impaired vitality—as, for instance, from alcohol—agents acting from within. Secondly, this led to digestive, gastric, duodenal, or intestinal disturbances, with the resulting changes in the liver. There might at least occur such a modification of reflexes in the duodenal end of the stomach on account of which either, on the one hand, the hepatic secretion was inhibited or, on the other, increased, leading thereby to modification of secretion on account of which cholelithiasis might develop. Third, cholelithiasis might result from circulatory conditions of the liver, the result of a weak heart, valvulitis, pericarditis, or perhaps an arteriosclerosis. For this reason not only the liver, but other organs of the body, their secretions and functions, were so modified that catarrhal conditions arose, on account of which cholelithiasis occurred. Again, infection might be a cause. If one realized these four predisposing factors one could really see that each had a field for medicinal or hygienic therapy. In accordance with one's judgment as to the factors causing cholelithiasis, one must lay down various plans of treatment. In general, it might be stated that cholelithiasis demanded hygienic treatment, the removal or modification of the cause as far as could be best brought about. But, further than that, there were certain specific measures. When catarrh continued there also obtained more serious inflammatory states, such as cholecystitis and pericholecystitis. First of all, then, after attempting to modify the cause, regulation of the diet must be considered one of the chief measures. Such a regulation of the diet did not require one to say a "liver diet," or "specific diet for the liver." The reduction of the diet was the chief essential. One should recognize the fact that there was a class of patients who were overfeeders—those who gave the liver too much to do—and in the larger proportion of cases cutting down the food to about one-half that usually taken was the first and best step toward the prevention and cure of cholelithiasis. There was no doubt but that, independently of the value of the waters, the cures secured at Carlsbad and other places were brought about by the reduction in the diet. If there were any specific lines of diet to be enjoined they must be those which were indicated more particularly by the state of the gastric and intestinal digestion. If there was a hyperacidity, then the diet must be so arranged as to meet this condition. If there was a subacidity, or added acidity, the diet must meet these conditions. If there was a dilated stomach, or evidences of intestinal indigestion, an enteritis, or mild catarrhal conditions of the stomach and intestines, treatment to relieve these conditions must be insisted upon. Hydrotherapy would avail much, whether used internally or externally. One might use either general baths or local baths. One might use alternately hot and cold douches over the liver. The use of hot compresses, alternating with cold ones, every one-half or one hour, or twice a day, was of value. Hydrotherapy could not be too strongly insisted upon. Such means as would continue hepatic drainage were important; hence there was value to be had in the use of abdominal bandage. This was not so valuable in fat as in thin subjects. In a large number of cases of cholelithiasis the frequency of the attacks had been lessened, and the severity perhaps had been modified, by wearing a properly constructed bandage. Unless the gallstones were doing mischief it was probably more conservative and better that these patients, if possible, be sent to Carlsbad or one of the resorts abroad, or to Bedford or Saratoga Springs in this country, so relieving any complicating conditions before the operative treatment was resorted to. Perhaps they had seen, as he had in a number of instances, a disappearance of the gallstone symptoms follow the patient's stay for the time being at least. As to the condition of the circulation, one must study most carefully the heart and blood vessels. If the liver contained a large amount of blood, one could get valuable suggestions as to the mode of treatment by a study of the circulation, which had much to do with the management of cholelithiasis. A weak or a dilated heart, with a low blood tension and evidences of a modification in the pressure on the venous side of the circulation, was indicated by the cardio-sphymograph; therefore, such remedies which modified, increased, or lessened the blood pressure were undoubtedly of value. It was important to note that the treatment of cholelithiasis meant not only the treatment of the liver or local disorder, but the treatment of the individual. With regard to drugs, there were very few that could be thought of in connection with cholelithiasis; none could be mentioned with any degree of confidence except those that were indicated after a careful study of the gastrointestinal tract, including the stools and gastric contents, indicated by a study of the circulation and of the blood as well. Alkalies should be first considered. If there was congestion and stasis, the old-fashioned remedy (muriate of ammonium), if it was not contraindicated, was valuable. This drug had a direct influence on the circulatory condition without a doubt. It also influenced the secretions. If there was any remedy which could allay catarrh and modify the secretions, it was this preparation. Again, there were the so-called biliary antiseptics, salicylate of soda and other salicylates. After the establishment of a biliary fistula, and watching the secretion of bile, it would be undoubtedly shown that the amount of bile was increased after the use of these remedies; also, the number of microorganisms became less. Whether this was due to the action of the drugs or to drainage he did not know. The use of phosphate of soda needed scarcely to be more than mentioned. With regard to the medicinal treatment of gallstones, any gallstone quiet in the gall-bladder and ducts could not be influenced by medicinal treatment. There was no known solvent for gallstones. Olive oil was thought of by those who believed in solvents, but Dr. Musser said he had never seen any relief of gallstones arise from the use of this agent. Sometimes there was a relief of the symptoms, but such relief, so far as he could see, followed because associated with the gallstones there was a hyperacidity; and, as a cause of this hyperacidity, there was either a simple gastralgia or pyloric spasm. And it was these conditions—or symptoms, rather—which were relieved by the use of the oil. It was only in a general way that one could hope for success in the management of cholelithiasis. It was not the treatment of the local process, but the broad, general management of the man who was sick.

Surgical Treatment of Diseases of the Gall-Bladder.—Dr. JOHN B. DEAVER of Philadelphia took up this part in the symposium. He said that to the surgeon diseases of the gall-bladder, excepting the malignant variety, were manifestations of some form of infection. Broadly speaking, it showed itself in two great varieties: the calculous and the noncalculous forms, cholelithiases with their various complications and sequelæ. The calculous form was the more common. In both forms were found various grades of inflammation of the gall-bladder. The main forms commonly met with were cholangitis, hepatitis, perforation of the gall-bladder, peritonitis, and adhesions in the upper abdomen. He said that if gall-bladder disease was to be regarded in its true light, as a local infection, with great power to spread and capable of prompt relief by the surgeon, then operation would no longer be delayed until hope had gone and surgery had become the last resort.

As calculous cholecystitis was of paramount importance, both by its frequency and the necessity for surgical treatment, he said he would first consider this form of gall-bladder disease. The indications for the *immediate* invasion by the surgeon were, first, the occurrence of any of the complications mentioned above, showing a spread of the infection, and, secondly, failure of amelioration of symptoms in obstruction of the common duct after a reasonable interval of treatment, which Dr. Deaver considered to be two or

three weeks. Certain other conditions demanded operation, but the necessity was not so great as in, first, repeated attacks of biliary colic or continued abdominal distress and indigestion; secondly, hydrops of the gall-bladder; third stone in the choledochus. Some of the contraindications to operation might be summarized as follows: Extreme age; organic lesions of the heart, lungs, or kidneys; marked cholemia; anemia of marked degree, or a greatly lessened coagulation of the blood. Dr. Deaver called attention to the remarks of Kehr, who stated that gallstone surgery indications were threefold: Removal of the inflammation causing the gallstones; removal of the stones; prevention of recurrences of the stones.

The following were the main facts in his own technique in gallstone operations: (1) After the incision had been made and the field of operation exposed, wall off this field from the general peritoneal cavity, and so guard against any possible spread of the infection. (2) Adhesions that were evidently impinging upon and interfering with neighboring organs must be removed; adhesions which were doing no damage should not be disturbed. (3) Only so much should be done as was required to meet indications present, especial care being taken when acute infection was present. (4) When that infection was present or suspected, and the gall-bladder was opened, it should be drained. His method of draining was the commonly used rubber-tube drain. The appearance of the bile was no criterion of its infectiousness. (5) The gall-bladder should not be removed unless it was so damaged as to render it incapable of function as a bile reservoir. If the fundus only was damaged, the gall-bladder should be resected instead of removing it entirely. (6) When the gall-bladder was removed, in the presence of infection, drainage of the stump of the cysticus should be made if possible. It was wiser to drain outside of the abdomen than to allow infected bile to flow into the duodenum. To drain one infected organ into another was unsurgical. So when the liver was infected and one had a suppurative cholangitis to deal with, the only chance for safety lay in direct hepatic drainage through the laparotomy wound. (7) When the gall-bladder was removed for disease in the absence of infection, drainage should be made by means of the cigarette drain, or piece of gauze passed through a split rubber tube to the stump of the viscus and the cystic duct. This guarded against hemorrhage and infection. (8) Choledochotomy without drainage should never be performed. (9) The stones present should be removed in order to make the operation successful. The after-treatment in most gallstone cases was simple—they got well by themselves. Occasionally certain conditions must be dealt with. Persistent vomiting might be treated by lavage and enteroclysis of salines. Dr. Deaver always immediately gave hypodermoclysis of 1,000 c.c. every four to six hours to insure a quantity of urine. If the heart became weak, digitalis was indicated. The drainage tube should be left in until its purpose had been accomplished. The diet should be restricted after operation. The bowels should be moved on the third day with castor oil. The technique of the operation was the same for noncalculous as in calculous cholecystitis, but one did not have so much trouble, but should confine themselves to combating infection. Malignant disease of the gall-bladder was evidently very rare. In a series of 217 gall-bladder cases operated upon by him, including 182 gallstone cases, Dr. Deaver's total mortality was 13.8 per cent. The mortality of the calculous form was 14.8 per cent.; in the noncalculous form it was far under 5 per cent. When acute infection was present, the rate of death with all operators arose to almost 20 per cent. The causes of death in over one-half the cases could be directly or indirectly attributed to the presence of infection before operation. The septic patient was a poor patient for operation. The general practitioner and internist should send their patients to the operating table earlier and in better condition; then the risks of surgery of the gall-bladder would be reduced to a minimum. The whole question depended upon the realization that they were dealing with infection; that it could be treated surgically, and that the sooner that was done the better the patient's chances would be.

Dr. E. W. Hedges of Plainfield, Dr. Charles P. Noble of Philadelphia, Dr. Emery Marvel of Atlantic City, Dr. Vanderveer of Albany, Dr. Philip Marvel of Atlantic City, and Dr. Philander A. Harris of Paterson discussed the papers read.

Tetanus and the Antitetanic Treatment.—Dr. Daniel Strock of Camden offered this communication. No matter how the serum had been used, the results had been disappointing, and probably it was the general impression of the profession to-day that in acute cases of tetanus antitetanic serum was of little value. He then called attention to the results of treatment in a few cases recently under his direction. Previous to this period he had been in contact with a number of cases of tetanus, following wounds of every description, and he had never known one to recover, no matter what the method of treatment had been. He began the use of the tetanus antitoxin about six or eight years ago. The patients then received one injection of 10 cm., to be followed by another the next day or the day following. In the years following the amount given in twenty-four hours was increased, until it reached a point where from four to six injections of 10 cm. would be given in twenty-four hours, covering a period of several days in succession. The results of this larger quantity appeared, in a few cases, to delay the approach of death, but did not affect the uniform termination of the disease. The last case treated during this period he identified as the first of a series of antitoxin injections, and this patient lived fourteen days and received the injections at more frequent intervals than any previously. Dr Strock decided that if the antitoxin possessed any virtue in fully developed cases it was exerted only in large quantities. This idea he then put into practice. Five cases were treated, and all presented typical avenues of infection, and all presented the classical symptoms of fully developed tetanus. Of these five cases, three recovered. In view of his past unfortunate experience with this disease, giving a mortality of 100 per cent. and extending over a period of many years, he said he was reluctant to believe that this last series of cases, with a mortality of 20 per cent., was simply an unexplained coincidence. As a result of his observation and experience in the use of the serum, he was of the opinion that much larger quantities must be used in the treatment of these cases, and also that larger initial doses must be given. He believed that at least 10 cm. should be given every hour in adults, until evidences of improvement manifested themselves. In conclusion, he felt encouraged to say that the pessimistic view entertained by the profession as to the use of antitetanic serum in fully developed tetanus would be modified in the future. Of the value of antitoxin in cases of suspected wound infection there could now be no reasonable doubt, and it would seem that the physician was culpable who failed to give the patient the benefit of this fully recognized immunizing agent, at the same time throughly cleansing the wound. All the antitoxin he had used had been introduced subcutaneously.

The Significance of Blood Pressure in Surgical Shock. Dr. A. J. Walschied of Hoboken offered this paper, which was read by title.

Election of Officers.—The Nominating Committee presented the names of the following men, who were elected to office: *President*, Dr. Edward J. Ill of Newark; *First Vice-President*, Dr. David St. John of Hackensack; *Second Vice-President*, Dr. Benjamin A. Waddington of Salem; *Third Vice-President*, Dr. Thomas H. Mackenzie of Trenton; *Corresponding Secretary*, Dr. Daniel Strock of Camden; *Recording Secretary*, Dr. William J. Chandler of South Orange; *Treasurer*, Dr. Archibald Mercer of Newark. Next place of meeting, Cape May.

Report of the Committee on Hygiene and Legislation. Dr. L. M. Halsey of Williamstown, chairman of this committee, said that the work during the session of 1907 had not been in vain, as they had been enabled to prevent the passage of any osteopathic measure. Personally, he wished to thank Senator Frelinghuysen for his untiring devotion to the interests of the medical profession of the State. There was now on the statute books of the State of New Jersey a pure-food act which was almost identical with the national pure-food measure, and the Senator from Somerset County should have unstinted praise for his exertion in placing this measure upon the statute books. There were several other bills of minor importance which were looked after by the committee. The committee were unanimous in their opinion that osteopathy should be recognized along the lines of the bill as introduced by Senator Frelinghuysen, and which passed the Senate, as being the very best solution of the difficulty, and one in which the interests of the medical profession were more nearly safeguarded than any other plan that had been proposed.

Report of the Committee on Medical Defense.—Dr. William G. Schauffler, chairman of this committee, reported to the society, advising the adoption of a scheme of defense based on that in use in the New York State Medical Society, modified to suit New Jersey conditions. A form of application was embodied in the report.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held April 18, 1907.

The President, Dr. John A. Wyeth in the Chair.

This meeting was held under the auspices of the Section on Dermatology, and the evening was devoted to "Recent Advances in the Knowledge of Syphilis."

The Morphology of the Spirochæta Pallida.—Dr. James Ewing presented this part of the topic, and illustrated his remarks with specimens and lantern slides. His paper was practically the one that he had already presented to the State Society.

The Inoculation Experiments.—Dr. Charles M. Williams read this paper. He said the experimental investigation of the problem of syphilis was blocked for many years by the lack of a susceptible animal. Metchnikoff furnished a secure foundation for future labor by selecting for his experiments the anthropoid apes. Metchnikoff's first article appeared in the *Annales de l'Institut Pasteur*, December, 1903, and was so epoch making that Dr. Williams quoted from it at considerable length. The higher apes, that is, the chimpanzee, the orang outang, and the gibbon were generally more susceptible than the lower, or at least they developed the chancre more readily. The incubation period varied from two to nine weeks, and its duration usually depended upon the virulence of the material used, and on the thoroughness of the inoculation. The initial lesion began as a small red spot, which soon changed to a papule, rarely a vesicle, then developed a scale, and might so remain as a firm scaly papule for days or weeks, and then slowly disappear, leaving a brown stain; or else it might form a shallow ulcer with an indurated base, exactly analogous to a typical human chancre in appearance, course, and duration. Thus far the different species of monkeys reacted in almost the same manner; but at this point they diverged, the higher apes, and especially the chimpanzee, presenting many of the symptoms of the disease as observed in man, while the lower apes showed no generalized eruption whatever, and only occasionally a few symptoms which might be called secondary. That this disease in monkeys was really syphilis, and not an accidental infection, was proven by the close correspondence with the disease as observed in man in all its important features. True tertiary lesions had not yet been certainly observed in apes. The material used for these inoculations was of various kinds, but all proven to contain the virus. Positive results were obtained eight times in twenty-four attempts to inoculate gummatous material, and in one of the eight cases the disease was twenty-four years old. The question of the infectiousness of semen was still undecided. Whether a qualitative change could be brought about by successive inoculations in lower apes was another question not yet definitely settled. Another important problem related to the question of the rapidity of the spread of the poison through the system, and two methods at once suggested themselves. First, the inoculation wound was excised, after varying intervals, or attempts made to destroy the virus in the wound by various means. From the experiments made it appeared that the virus might penetrate beyond the reach of ordinary interference in a very short time, but that as a rule about a day was required. The second method was by means of inoculation with the blood and internal organs of animals killed at varying intervals after infection. It was altogether probable that the virus was spread through the body even earlier than the figures given indicated, but as yet the experiments were too few to settle the question. Closely allied with this problem was the question of reinfection. The older the syphilis the less marked was the lesion caused by secondary inoculation, so that in the full secondary period it often failed altogether, and was much less conspicuous when it did appear. Subcutaneous, intravenous, and intraperitoneal inoculations had been repeatedly attempted, but always without success. Dr. Williams closed his paper by saying that there were still many gaps in our knowledge of syphilis, but that he confidently expected to see them filled by the continuance of the work so well begun.

Serum Diagnosis and Serum Therapy.—Dr. Sigmund Pollitzer read this paper. He said that with the great movement of the past decade toward serum diagnosis and serum therapy in infectious diseases, it was only natural that attempts at employing some of the methods that had proven valuable in other diseases would be made in the cases of syphilis. The first really important work was that of Kraus and Spitzer, who based their method on the theory of the production of antibodies through the injection of large quantities of specific toxins. They practised subcutaneous injections of increasing doses of suspensions of finely divided chancres into patients as soon as possible after their infection with syphilis. Of twenty patients treated eleven developed secondary symptoms as in the normal course of the disease, two showed only a rudimentary development of secondary lesions, and seven (35 per cent.) showed no further symptoms whatever for a period of observation extending in some cases over two years. Experiments were at present under way with animals normally refractory to syphilis in the hope of producing sera. As bearing on the question of specific substances in syphilitic blood the observations of Hoffman and Provazel were mentioned. Wassermann, Neisser, and Bruck were the first to bring syphilis in line with other infectious diseases in relation to the great working hypothesis of immunity, Ehrlich's side-chain theory. They proposed to utilize the method of fixation or anchoring of the complement for the purpose of testing the presence of syphilitic antigens and antibodies in infected individuals. Dr. Pollitzer then entered into the details of this method. This method of complement fixation, or "anchoring of the complement," was proven to hold true for anthrax, plague, typhoid, diphtheria, tetanus, tuberculosis, etc. It went to prove that they were dealing with broad biological principles of universal application. The determinations were carried out by exact quantitative methods. The precise amount of complement required to reactivate

a given hemolytic serum was first determined. In applying this method for the determination of specific syphilitic substances Wassermann, Neisser, and Bruck did as follows: Apes were injected with syphilitic material consisting in a series of cases of the blood of secondary syphilities or of watery extracts made from primary syphilitic buboes, from condylomata, from organs, or bone marrow of hereditary syphilitic infants or fetuses, or of the organs or marrow of apes killed seven or eight weeks after infection with syphilis, and their serum, inactivated by heat, was mixed with fresh extracts of chancres or syphilitic organs. Such serum was presumed to contain syphilitic antibodies and the fresh syphilitic extracts the specific antigens. To this mixture some fresh pig's blood containing complement was then added and the mixture allowed to stand for a short time to afford an opportunity for the union of antigen, antibody, and complement to take place. Then a second mixture of inactivated hemolytic serum and appropriate red blood cells was added to the first mixture and hemolysis failed to take place because, of course, the added complement had been anchored by the first mixture and was, therefore, not free to reactivate the hemolytic serum. This experiment was a success and it was definitely established (1) that the immune serum of syphilis contained antibodies, and (2) that the syphilitic extracts contained antigens. By way of control it was shown that (1) the immune serum of apes gave the reaction only with syphilitic material of man or apes, not with non-syphilitic material of either; (2) that normal non-syphilitic ape-serum was ineffective with syphilitic material; (3) that serum of apes treated with extracts from the organs of non-syphilitics gave no reaction with known syphilitic material. Finally, the immune serum worked equally well whether prepared with human or simian syphilitic material, a striking corroboration, by the way, of the identity of human and simian syphilis. This, then, was a specific sero-diagnostic reaction for syphilitic material which enabled them to determine in the laboratory *in vitro* the presence of specific antibodies against the syphilitic organism in human serum, or in prepared immune serum, and second to show the presence of syphilitic substances in a given organ. Thus it had been shown that specific antigens were present in the placenta of syphilitic women, and in a few cases the presence of syphilitic antibodies were shown in the circulating blood of syphilitics.

The Practical Application of the New Knowledge.—Dr. Boleslaw Lapowski read this paper. The facts known regarding the *Spirochæta pallida* were (1) that such a structure had been found on the surface and in the parenchyma of all lesions of acquired and congenital syphilis; (2) it had been found on the surface of lesions produced by inoculation of syphilis into higher and lower apes and into the cornea of rabbits; (3) that it was not found in non-syphilitic lesions. The identity of the *Spirochæta pallida* found on smears with the supposed *Spirochæta pallida* in sections of syphilitic organs was questioned by many, who held that the structures seen in tissues by means of Levaditi's silver method were particles of tissue, sometimes connective tissue fibers, sometimes nerve fibrils, and cell contours, which presented a morphological appearance not unlike that of *Spirochæta pallida*, owing to pathological processes in the tissues, and to the action of the silver impregnation, used to bring into view the supposed pallida. The real advance was made by the successful inoculation of syphilis into apes. If an ape was inoculated a second time before the appearance of the chancre of the first inoculation, or even some time after its appearance when a certain incubation period had elapsed, a second chancre would appear at the point of reinoculation. No result could be obtained from reinoculation during the development of the secondary eruption. Reinoculation was tried in every period of syphilis and successfully achieved in every stage, except during the height of the first early eruption. The system reacted upon such second inoculation in a peculiar manner, that was, it responded to reinoculation with external virus in the same manner as it reacted to its own syphilitic virus. That the reaction was due solely to the newly introduced virus was proven by the failure of producing such an effect by the introduction into the syphilitic organism of non-syphilitic material. These results were obtained from experiments carried on in human beings and in apes infected with syphilis. They demonstrated that in apes and in humans a reinfection was possible, not only during the first incubation, but through the whole development of the disease, the system reproducing lesions of that stage in which the patient was during the time of reinfection. The fact that a syphilitic patient in the active stage of the disease could react even in a slight degree upon the introduction of new syphilitic virus was in gross contradiction to their accepted conception of immunity in syphilis. Dr. Lapowski emphasized the point that, owing to the prevalent idea that syphilitics were absolutely immune to new infection, patients very often exposed themselves to a possible fresh infection. This idea of absolute immunity was erroneous. The skin was not immune. Does syphilis begin with a chancre? The reported clinical observations, where early manifestations of syphilis followed lesions without characteristic symptoms of a chancre were to be regarded as correct; while reports of syphilis developing without the appearance of a primary lesion were open to question, the chancre having been overlooked by the observer. Can syphilis develop without involving the skin and the visible mucous membranes? Clinically the fact of the appearance of these manifestations played an important part in the diagnosis of syphilis. The experimental inoculations demonstrated that syphilis in the lower ape was generalized, involving some internal organ, as the spleen, bone-marrow, testicles, and glands, without producing any manifestations upon the skin or mucous membranes. In view of this fact conclusions as to the character of doubtful primary lesions should not be drawn from the non-appearance of early skin manifestations in patients with such lesions. Upon the rapidity of generalization of the virus depended the result of excision. Inoculations demonstrated the futility of excision eight hours after infection. In regard to the syphilis producing agent, inoculation experiments demonstrated that it existed not only in the fluids of the body, blood, and spinal fluid, and all lesions of the early period of the disease, but also that the lesions of the late period, gummata, contained the active living virus, and that the virus was of the same character, having the same properties in a chancre which appeared say seventeen days after infection, as in a gumma which developed seventeen years after infection, showing that it did not undergo a qualitative change during its stay in the system. The demonstration of the infectiousness of gummata should induce physicians to hasten the process of their healing. Nothing definite was demonstrated by the inoculation experiments regarding the virulency of sperma and ovum *per se*. The part which maternal and paternal transmission played in hereditary syphilis was still open to question. Nearly all the organs of a hereditary syphilitic fetus contained the active virus; even the nasal discharge was infectious, a fact to be borne in mind when the child was wet-nursed. Every fetus and every infant which died shortly after birth without evident cause should arouse suspicion in the physician's mind of the presence of syphilitic infection of the parents, even when both parents and infant present no visible signs of syphilis. Serum therapy had not proven a success, as it was impossible to obtain an attenuated virus. They must

still rely upon mercury in the treatment of syphilis; the salutary specific action of mercury must be brought to bear upon the virus intermittently for a protracted period in both stages of the disease; that is, in tertiary manifestations mercury, and not potassium iodide, was the remedy par excellence.

Dr. Simon Flexner said that the question still remained unsettled and would no doubt remain unanswered for some time to come. So far as the etiological factor of syphilis was concerned, properly there were two camps: first, those that had a strong conviction that the agent had been discovered in the *Spirochæta pallida;* the second camp was still in doubt as to this causative factor. Personally he belonged to the first camp, for the evidence from a pathological point of view was strong in its favor. The only set of facts which would seem to lead to doubt was the restricted distribution of the organism. When compared with other pathogenic organisms one must decide that there was a great deal more to be said in favor of the *Spirochæta pallida* belonging to this class than could be said against it. In regard to the application of the method of demonstrating the presence of antigens and antibodies as a satisfactory and reliable means of diagnosis of syphilis, Dr. Flexner said that in theory the reaction was one which supported the present contention that this microorganism of syphilis was the one which yielded toxin or antigen and was bound up more or less with the view of the *Spirochæta pallida* being the microorganism. He said that the pallida stain was one that was easy of application; with a slight modification it was possible in ten or fifteen minutes to demonstrate its presence in smears. The chief part of the modification was not to fix the preparation with alcohol or osmic acid; the method was one in which a mordant was used. Not only did the mordant fix the smear and impregnate better, but the stain was more intense. Recently he had had sent to him an infant, still born and syphilitic, and in whom was demonstrated the pallida. He asked regarding the history of the mother and nothing was given that was at all definite. The patient was in the hospital and was gone over very carefully clinically, but nothing was discovered on the body surface. There never had been a sore throat. When the mouth was opened, however, a very slight abrasion upon the side of the tongue was found. It was cleaned by scraping, smears were prepared, and the pallida demonstrated. The infant was clearly syphilitic, and the mother had but this single lesion. It seemed to Dr. Flexner that the evidence was strong in favor of the *Spirochæta pallida* being the etiological factor of lues.

Dr. William S. Gottheil was glad that an easy method of staining had been found, because he had been impressed not long ago by the failures of professional pathologists connected with the largest institutions in demonstrating the *Spirochæta pallida* in specimens when it was known to be present. He was glad to hear that the new method was a practical one. After all scientific results must be judged by practical findings. Even if it had been demonstrated that the gumma contained the *Spirochæta pallida*, the fact remained that, as seen to-day, it was not an infectious lesion and did not produce syphilis. If a modified form of the disease was thus produced the ravages of this disease would be enormous.

Dr. Ira Van Giesen could see nothing which proved that the *Spirochæta pallida* should be regarded as the causative agent of syphilis.

Dr. Edward L. Keyes, Sr., said he had seen syphilitic monkeys in the Pasteur Institute in Paris last summer, and the observations made showed that the monkeys did not have true syphilis.

Dr. Williams, Dr. Pollitzer, and Dr. Lapowski closed the discussion.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending July 20, 1907:

	Cases	Deates
Tuberculosis Pulmonalis	308	152
Diphtheria	304	29
Measles	414	24
Scarlet Fever	231	14
Smallpox	..	..
Varicella	44	..
Typhoid Fever	54	9
Whooping Cough	32	6
Cerebrospinal Meningitis	13	12
Malarial Fever	.....	.....
Totals	1400	246

Helath Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended July 19, 1907:

		CASES.	DEATHS.
SMALLPOX—UNITED STATES.

THE EVOLUTION OF GASTROENTEROLOGY.*

BY HENRY WALD BETTMANN, M.D.,

CINCINNATI, OHIO.

THE most important change in the spirit of internal medicine during the past quarter of a century has been the swinging of the center of gravity from the pathology of structure to the pathology of function. Twenty-five years ago pathological anatomy and histology were beginning to lose their force as a means of medical progress. They were becoming sterile from overcultivation, and had ceased to reveal new truths. An entirely new point of view became absolutely essential to vitalize research. This new point of departure was afforded by bacteriology, which in an amazingly short period became a well-organized science. At the same time, rapid advances in organic chemistry rendered possible the development of new methods of research, and chemical pathology became a fertile department. Chemistry and bacteriology have rejuvenated pathology, making it seem like a young science capable of unlimited development and growth. Every branch of internal medicine has been quickened by the change. The post-mortem specimen has lost not its basic importance but its dominating influence over clinical ideas. Research has turned from the autopsy room to the laboratory of animal experimentation, and to the clinic itself, in its study of the disorders of function during life. Surgery has come to the aid of internal medicine by revealing pathological changes in their earliest stages, often offering the advantages of what might figuratively be called human vivisection. Medical nomenclature has of necessity reflected this change of attitude, and new terms expressing pathology of function have been created, such as renal incompetence, neurasthenia, hyperthyroidism. The study of disordered function has naturally strongly emphasized the necessity of a knowledge of normal function, and physiology has come into more intimate relation with clinical medicine than ever before in history. As a result, a new impetus has been given to research work in physiology, and many chapters have been rewritten within the last two decades. No part of the body has been so vitally affected by this progress in method as the organs within the abdomen. A generation ago our knowledge of the digestive organs was exceedingly imperfect. Physiology of the stomach had advanced but little beyond Beaumont; of the pancreas beyond Bernard. Clinical pathology had little definite to offer beyond the conception of cancer, ulcer, and catarrh. Knowledge of the motor functions of the stomach and intestines was hazy and imperfect; the interrelation of the chemical secretions was unknown; the influence of bacterial life undreamt of. It has been only within the past decade that scientists and clinicians alike have realized that the entire science of the digestive organs, sometimes called gastroenterology, is in need of complete revision in the light of modern revelations. The new knowledge obtained from physiological experiment, from bacterial investigation, from chemical physiology and pathology, and from surgery, must be brought into harmony with the facts of clinical experience and organized into practically a new art. From this point of view the formation of a society like our own has became an absolute necessity, in order that the new facts revealed by scientific investigators in the various correlated departments may be quickly brought together and made available and profitable for the clinic.

Our knowledge of the motor activity of the stomach has become clear only during the past ten years. John Hunter and, after him, Sir E. Home undoubtedly recognized the fact that the stomach was physiologically divided into two distinct parts, and Beaumont, from direct observation, described well the distinctive activity of the pyloric half of the stomach. Nevertheless, the exact mechanism of the muscular activity of the stomach has become part of our general knowledge only since it has been unmistakably demonstrated by animal experimentation. Hofmeister and Schütz showed on the cut-out stomachs of recently killed dogs that the pyloric half was the true motor part of the stomach. Rossbach noted that the fundal portion remained almost passive during digestion and that peristaltic waves began at the antrum pylori. Moritz made manometric observations on the human stomach, and also demonstrated the passivity of the fundal half during digestion and the rhythmic character of the contractions of the pyloric half. Roux and Balthazard were the first to employ successfully the *x*-ray in man and animals, but to Cannon we owe the clearest and most complete description of the muscular activity of the stomach, under normal, artificial, and pathological conditions. We have learned from Cannon that depressing emotions and asthenic conditions of the general system delay or even stop gastric peristalsis. Handling of the intestines inhibits gastric peristalsis, and operations on the upper jejunum cause closure of the pylorus for at least six hours, or while primary glueing takes place at the site of the operation. Through Cannon also we have advanced a step farther towards a complete understanding of the marvelous mechanism of the pylorus. Hirsch and von Mering independently demonstrated that the nervous impulse for the closure of the pylorus was a reflex one, having its origin in the duodenum. Serdjukow, working in Pawlow's laboratory, showed that the reflex was due to the acid reaction of the chyme, and that the pylorus remained closed after the passage of chyme until the same was neutralized in the duodenum. Sindwarew showed a similar mechanism for fats in the duode-

*President's address, read at the tenth annual meeting of the Gastroenterological Association at Atlantic City, June 3, 1907.

num. Cannon was the first to suggest that the relaxation of the pyloric sphincter was due to the appearance of free HCL in the stomach, and in this way he explained the rapid passing from the stomach of foods (*e.g.* carbohydrates) which have little binding power on the HCl, and the long stay in the stomach of albuminous foods, like eggs and meat, which delay the appearance of free acid by combining with the HCl until saturated. Cannon's explanation is ingenious and illuminating, but is not altogether in accord with certain clinical observations, such as the rapid emptying of the stomach in achylia, the slow passage of certain fruits from the stomach, the passing of alkaline waters through the pylorus before they are neutralized, etc. It probably represents part of the truth but not all of it.

Our knowledge of the movements of the intestines is very recent. Landois's Physiology of twenty years ago describes rather crudely the peristaltic waves in the small intestine. "The movements," says Landois, "cease during sleep." No mention is made of the segmenting movements. The movements of the colon are said to resemble those of the small intestines, but are more sluggish and feeble. Twelve years ago Nothnagel's "Diseases of the Intestines" was published as part of his "Encyclopedia." An entire chapter is devoted to the movements of the bowels. Nothnagel described both the true peristaltic waves and the pendular or swaying movements of the intestine. He did not recognize the segmenting effect of the latter, and only guessed at their true significance, and he knew absolutely nothing of the normal antiperistalsis in the large bowel. For our knowledge of the segmenting movements in the small intestine and the antiperistalsis of the proximal colon, we are indebted to Cannon. With the *x*-ray, Cannon demonstrated that the pendular movements of the small intestines are accompanied by rapid waves of contraction whose effect is to break up the contents of the intestine into separate masses, rapidly varying their position and shape, and thus to bring the bowel contents into most intimate contact with the mucosa. These movements are oscillatory but have no propulsive effect, and are according to Starling purely myogenic in character. In 1902 Cannon described the antiperistalsis as the normal movements of the proximal colon. By means of antiperistaltic waves originating in the ascending colon the bowel contents coming from the ileum are pressed back into the cecum, and are churned about until most of the fluids are completely absorbed. Only gradually are the slowly hardening contents propelled into the transverse colon and past the splenic flexure. Here the antiperistaltic and churning movements are slight, the propulsive movements predominating. Under normal conditions the semifluid contents of the cecum cannot reenter the ileum on account of the obliquity of the ileocecal orifice and the tonicity of the ileocolic sphincter. The innervation of the ileocolic sphincter seems to differ from that of the small intestine, inasmuch as it is unaffected by stimulation of the vagus nerve, but excited to strong contraction by stimulation of the splanchnics. The small intestine, on the other hand, is inhibited by stimulation of the vagus and relaxed by stimulation of the splanchnic. The true peristaltic waves in the small intestine are occasioned by the innervation of Auerbach's plexus, which according to Starling may be regarded as a lowly organized nervous system with practically one reaction. This one reaction has been designated "the law of the intestine," and can be summarized by stating that stimulation at any portion of the small intestines causes contraction above the point of stimulus and relaxation below it.

The movements of the intestine under certain surgical conditions have also been made the subject of special study by Cannon and Murphy. These investigators have shown that end-to-end anastomosis of the severed gut produces no obvious inefficiency; that lateral anastomosis is followed by the accumulation of food at the site of union; that etherization and exposure of the intestines to the air produce only a slight retardation of gastric and intestinal peristalsis, whereas handling of the gut seriously interferes with the onward passage of the stomach and bowel contents. Rough handling may lead to extreme sluggishness of the intestines, so that food reaches the cecum many hours beyond the normal.

Our knowledge of the chemistry of digestion has been enormously clarified by the discovery of the relation which exists between the various parts of the digestive canal. The earlier physiologists believed that the mere presence of food in the stomach or intestine reflexly stimulated secretion. The facts are not so simple. Pawlow has shown us that gastric juice is secreted before the food enters the stomach, and that in fact its flow may be excited by the mere thought of savory food. This is obviously a delicate reflex mechanism, the afferent link of which comes from the nerves of the mouth or from the centers of ideation in the brain, the efferent impulse being carried by the vagus. There is no doubt, however, that the presence of food in the stomach itself causes the flow of additional gastric juice. Walter Gross has recently shown that the flow can be produced by meat extract introduced into the duodenum.

Within the last few years we have learned how the entrance of chyme into the duodenum excites the flow of pancreatic juice. Both Claude Bernard and Pawlow thought that food in the duodenum aroused these secretions reflexly through the nervous system. Wertheimer and Popielski (working independently) proved that acids in the duodenum caused the secretion of pancreatic juice after section of the vagi, and destruction of the splanchnics and the spinal cord. Starling and Bayliss proved that the relation between the duodenum and the pancreas was of a chemical and not of a nervous character, and that the real exciter of pancreatic secretion was a chemical substance produced by the action of HCl on the duodenal mucosa. This substance, called secretin, when injected into the jugular vein, causes profuse secretion of pancreatic juice within two minutes.

This specific substance has not yet been isolated. It is not destroyed by boiling, even in strong acid; it is not affected by gastric juice; it is easily diffused through animal membrane; it is not precipitated by the usual reagents for proteins and peptones. It is, therefore, a relatively stable substance of low molecular weight. It can be obtained from the mucosa of the duodenum and jejunum, but not from the lower ileum, the colon, or any other part of the body. Secretin doubles the secretion of bile. It also stimulates the flow of succus entericus in the duodenum and jejunum. There is no doubt that the lower ileum differs in function from the upper part of the small intestine. Above, secretion is the chief function; below, absorption. The secretion of succus entericus is also stimulated by the presence of any solid substance within the bowel, the secretion occurring through the influence of the local nervous mechanism (the plexus of Meissner).

The intestinal juice contains two other ferments which are engaged in the process of proteolysis, enterokinase, and erepsin. The former activates the pancreatic juice by transforming trysinogen into trypsin; the latter has the power (which is shared by many other juices in the body) of hydrolyzing albumoses and peptones into amino and diamino acids.

Coincident with this growth of our knowledge concerning the physiology of the digestive tract, there has come about a gradual evolution of our clinical ideas. Fifty years ago von Frerichs stated that insuperable obstacles would, for a long time to come, prevent us from gaining a clear understanding of the functional disturbances of the stomach.

Yet Kussmaul, ten years later, blazed the way for this knowledge by introducing the stomach tube into general practice. Kussmaul's classic article on the use of the stomach pump in dilatation of the stomach should be read to-day by every physician, whether internist or surgeon, who is interested in the treatment of pyloric obstruction. On the basis of twelve cases treated by lavage, Kussmaul described the production of pyloric obstruction by the healing of pyloric ulcers, the subsequent dilatation of the stomach, the complete symptomatology including visible peristalsis, and the frequently permanent cures by means of dieting and lavage.

Leube quickly recognized in the tube an invaluable means of studying the functional activity of the stomach whether chemical or motor. In 1879, von den Velden, one of Kussmaul's assistants, made his epoch-making discovery of the deficiency of HCl in gastric carcinoma, and Riegel later found the almost constant occurrence of hyperchlorhydria in chronic ulcer. The motor functions early attracted the attention of clinicians, and in 1878 Rosenbach invented the term "gastric insufficiency" to designate deficient motor power of the stomach.

Thus the foundations were laid for all the subsequent study of the functional activities of the stomach. The next two decades witnessed great industry in devising ways and means of gaining a clear insight into the shape, position, and size of the stomach, and of simplifying the means of chemical analysis. Fenwick in England and von Frerichs in Germany invented the artificial inflation of the stomach with effervescent mixtures. Numerous less important means were discovered for mapping out the position of the curvatures. In 1883 Meltzer called attention to the value of studying the sounds of deglutition. Gastrodiaphany was introduced in 1889 by Einhorn.

Auscultatory percussion was also soon used, its advantages having been first emphasized by Benedict. The importance of clapotage was emphasized by Bouchard in 1884, he, however, vastly overrating its importance. Strange to say, the use of the stomach tube for diagnostic purposes did not become popular until after 1885. Gunzburg's reagent was first described in 1887. Uffelmann's dates back to 1880. Infinite pains were taken by German chemists and clinicians in refining the chemical methods of qualitative and quantitative analysis.

Looking backward over the decade from 1880 to 1890 we see what an enormous amount of painstaking effort was required to produce the few uncomplicated tests in use to-day. Since 1890 there has been a marked tendency to simplify methods, to reject all pedantic distinctions, and to make observations more practical in their nature. Toepfer's reagent for quantitative analysis, introduced in 1894, has been universally adopted. Great refinements of chemical analysis have been discarded. The static conditions of the stomach, size, shape, position, and capacity attract less and less attention, while the dynamic powers, secretory activity, and propelling power have come more and more into the foreground. We have learned that small stomachs may be incompetent, while large ones may have perfect muscular power. We speak, therefore, less of the size of the stomach and more of its functional activity. The term dilatation threatens to be displaced by motor insufficiency, myasthenia gastrica, and ischochymia.

There has grown a slight tendency, especially from the surgical side, to minimize the value of all the chemical tests. Nevertheless, every practitioner cannot fail to recognize their indispensable utility in diagnosticating functional from organic disease, in differentiating ulcer from cancer, in making certain specific diagnoses, such as achylia gastrica, nervous hyperchlorhydria, etc. The chemical tests for occult blood in the feces have already taken an assured position among our chemical methods. On the other hand, our attitude towards the total functional activity of the stomach has undergone considerable modifications. Gray's Anatomy of 1884 states that the stomach is the most important organ of digestion. The relative unimportance of gastric digestion has been gradually revealed to us since then by the study of patients after gastroenterostomy, of cases of achylia, and of the results of resections in man and animals.

Nowhere can the modern tendency to express diseases in terms of function rather than in terms of structure find better illustration than in the diseases of the intestines. Nothnagel, in 1884, impressed upon the profession the necessity of a careful and systematic study of the feces as a means of understanding intestinal disorders. For various reasons, careful examination of the feces has not been widely adopted by clinicians as a means of diagnosis. Up to within very recent times the macroscopic search for pus or blood and the microscopic search for amebæ have constituted the sum total of clinical procedures. The mastery obtained over gastric disorders by a study of gastric functions has recently stimulated investigators to apply similar methods to the study of the bowels. The task, however, is a difficult and complicated one. The study of the feces offers the only opportunity of approaching the subject, but the feces represent an end-product of many different processes. The secretions of the liver, pancreas, and intestinal mucosa, are poured into a common canal and act upon food which has already been subjected to two digestive juices. The products of digestion are absorbed, but the residue falls a prey to the action of the intestinal bacteria and is mixed with substances excreted into the bowels through the intestinal mucosa. Chemical methods of studying the feces have as yet produced little that is of practical value. The tests for occult blood, the sublimate test for hydrobilirubin, and the fermentation test for carbohydrates may be mentioned as exceptions. Bacteriological study of the feces is just entering upon what promises to be a most productive career.

The best clinical advances have been made thus far by studying the feces after certain test diets. The Schmidt test diet has found the widest acceptance in America as in Germany; in England the mixed diet recommended by Harley and Goodbody has been extensively used. Einhorn has sought to simplify the methods by giving certain foods attached to beads which can easily be regained in the stools. This plan offers obvious advantages over all others, and promises to become widely adopted.

Some of the most important conclusions reached by Schmidt are as follows: Mucus in the stool is a positive sign of inflammation of the mucosa (except in cases of mucous colic). Visible mucus nearly always comes from the colon. If mucus comes from the small intestine it may appear in very small flakes crowded with bacteria or cell-nuclei. In ulcerative processes purulent mucus is discharged, but rarely pure pus. A negative sublimate test almost invariably indicates complete occlusion of the bile duct. As about 20 per cent. of the dry substance of normal stools is fat, only a considerable increase can be practically recognized. Fatty stools are abundant in quantity, light in color, and acid in reaction. They occur in deficient flow of bile, in disorders of pancreatic secretion, and in certain rare intestinal disturbances. Connective tissue remains in the stools indicate an interference with gastric digestion. Muscle fibers show a deficiency of intestinal digestion. Starch indigestion is usually due to a defective secretion of succus entericus.

The intestinal disorders of digestion may be classified according to their etiology as gastrogenic, hepatogenic, pancreatogenic, or essential intestinal. Gastrogenic intestinal disorders are very frequent, *e.g.* the well-known diarrhea of achylia gastrica. Connective-tissue remains are found in the feces in many gastric conditions. According to Schmidt, the diarrhea accompanying gastric disease is not due directly to the diminution or absence of HCl. When gastric secretion is deficient, the fermentation and putrefactive products pass more readily into the bowel. Raw connective tissue cannot be digested by the pancreatic juice, and when fat and muscle fiber protected by connective tissue pass into the bowel they become the ready nidus for putrefying organisms.

When bile cannot enter the intestine the only important disturbance is the interference with the absorption of fat. According to Schmidt, and contrary to the common opinion, acholic stools neither ferment nor putrefy, nor does the absence of bile from the intestine lead to constipation.

It is difficult to recognize the disturbances of digestion which are due to imperfect activity of the pancreas. When the pancreas is totally destroyed or occluded, fatty stools are passed which contain bile pigment, globules of fat, and muscle remnants, and which rapidly putrefy. Methods have been devised for estimating diminished secretion of pancreatic juice. Sahli's glutoid capsules are said to resist gastric digestion and to fall a prey to pancreatic digestion, but this method will always be an imperfect one. Schmidt sought to test the digestive activity of the pancreas by the study of the nuclei of animal tissues (marbled beef). Only pancreatic juice can digest nuclei. The reappearance of most of the nuclei in the stools indicates an impairment of the pancreatic function. Einhorn makes use of this principle in his bead test, by attaching to one bead a little cheesecloth bag containing thymus gland.

In 1902 Strasburger called attention to the fact that many cases of constipation are due to a too perfect digestion. Too good a digestion leaves too little residue. As a result, the number of intestinal bacteria diminishes, the products of putrefaction are less, and the normal stimulus to peristalsis is thus removed. An effort to overcome constipation by introducing yeast and cultures of *B. coli* failed completely. In the past we have tried to cure constipation by increasing the carbohydrates in the diet. Schmidt suggests that better results might often be obtained by adding an excess of fats, and Dörfller, in 1900, successfully adopted this method by adding butter to the diet of infants, and thus overcoming the constipation.

An entirely new field of clinical medicine has been opened by the study of the intestinal bacteria. No department of medical science is richer in possibilities of revelation than this, and it seems probable that many of the so-called metabolic diseases will be found to have their origin within the intestine. The bacterial flora vary at different ages in the same individual, in the same individual under different forms of diet.* The meconium is sterile. The intestinal canal of normal human nurslings is the habitat of a fairly uniform bacterial flora. The mouth and stomach contain relatively few bacteria. The duodenum and jejunum are remarkably free from them. At the lower level of the ileum, there is almost regularly an abrupt increase. In the cecum, the number of bacteria is enormous. In the ileum, the gram-negative bacilli predominate (*B. coli* and *B. lactis aërogenes*). In the colon the gram-positive bacilli gain the upper hand, chiefly of the *B. bifidus* group, and in the rectum these seem to appear almost in pure culture. It is probable that most of the infantile bacteria are introduced through the mouth, but that *B. bifidus* gains entrance through the anus. Other important but much scarcer bacteria in the infant's intestine are the *B. acidophilus* (Maro) and *B. aërogenes capsulatus* (Welch) sometimes *B. putrificus* (Bienstock), the last two of which are putrefactive anaërobes, and grow more numerous as the children advance in years. These bacteria may increase greatly in middle life and their putrefactive products absorbed into the blood may cause various clinical manifestations. As old age approaches, putrefactive processes within the intestine are apt to become better established. Herter states with considerable assurance that "the onset of senility may be distinctly accelerated through the development of intestinal infections in which the putrefactive anaërobes are prominently represented."

In normal adults the bacterial flora of the intestines have been carefully studied. The chief obligate forms are *B. lactis aërogenes*, which predominates in the upper part of the small intestine, and the *B. coli* group, which is the chief occupant of the colon.

It is probable that the intestinal bacteria are not essential to healthy life. The chief value of these obligates lies probably in their potential capacity to check the growth and development of harmful bacteria. In the cecum and ascending colon, bacteria reach their most luxurious development. Further along in the colon the *B. coli* group tends to die out, chiefly because their soil becomes exhausted, but partly because of the formation of certain inhibitory substances such as indol, acids, and phenol.

This explains the fact that the stools following the use of purgatives are often richer in living bacteria than the normal stools. The relation of the intestinal bacteria to the formation of oxalic acid, acetone, certain diamines, cholin, neurin, sulphur compounds, and various aromatic bodies has yet to be worked out conclusively. Already numerous cases have been reported of systemic poisoning due to the absorption of one or the other of the above poisons from the intestinal canal. Individual susceptibility plays a strong rôle. Much patient research work is here needed. Already an attempt has been made to place the pathological putrefactions within the intestines upon a solid clinical basis. Herter recognizes three common types: (1) the in-

*Free use has been made of Herter's recent book on the intestinal bacteria.

dolic type; (2) the saccharobutyric type; (3) the combined type. In the indolic group there is probably an invasion of the ileum by a member of the *B. coli* group which attacks hydrolyzed proteids and forms indol. This process is common in cases of occlusion of the bile duct and probably frequently occurs in childhod. The saccharobutyric type is common in adults. It is due chiefly to an infection with *B. aërogenes capsulatus,* which may be associated with other bacteria. The stools in these cases are apt to be light in color, due to the admixture of fine air-bubbles; they float on water; they may smell of butyric acid; the reaction may be acid, neutral, or alkaline; they contain little or no indol. The patients usually suffer in nutrition; many develop anemia; they cannot tolerate acids or carbohydrates. Nervous symptoms as a rule are not prominent. There is often a tendency to diarrhea. The combined type includes those cases in which the putrefactive anaërobes are very abundant and in which there is a persistent indicanuria. Symptoms of nervous depression and of muscular weakness predominate in this condition, and pernicious anemia may result from it. In extreme instances operations for the elimination of the colon might seem indicated. Appendicostomy might answer the same purpose.

The orthopedic surgeons are beginning to look to the intestinal canal as the remote cause of many joint lesions, the etiology of which has hitherto remained unexplained. Arthritis deformans and certain types of chronic infectious arthritis are thought to be due to certain poisons circulating in the blood and resulting from intestinal putrefaction. At the recent meeting of the American Orthopedic Association, Hoke of Georgia related his efforts in these cases to overcome the intestinal putrefaction by the administration of sour milk products. As is now well known, an acid reaction restrains the growth of putrefactive bacteria. A milk diet counteracts putrefaction by favoring the growth of the lactic acid bacteria which displace the putrefactive organisms.

The contributions which surgery has made to the department of gastroenterology are so numerous and important that they may not be omitted from this review. Leaving aside the triumphs which surgery has earned for its complete mastery over appendicitis, its dramatic saving of life after visceral perforations, its victory over the formerly invariably fatal cases of acute pancreatitis, its cure of chronic pancreatitis, its optimistic attack on intraabdominal cancers, surgery has also had a marvelous effect in stimulating research work on the abdominal organs.

Surgeons have discovered the remarkable absence of pain attending the handling of the abdominal viscera during operations and concluded from this that normal and even inflamed viscera could not be the seat of pain. This view received general acceptance until Meltzer and Kast demonstrated that this apparent painlessness is in all probability due to the use of cocaine. Gastric surgery has tremendously stimulated interest in gastric ulcer and cancer, pyloric obstruction, gastric hemorrhage, and displacements of the stomach. Abdominal surgery has revealed the tremendous number of cases in which gastric symptoms are extragastric in origin, and our conception of the clinical pathology of the gall-bladder has been revolutionized in the last ten years. To this end the internists, surgeons, bacteriologists, and chemists have cooperated. There is little reason to doubt the conclusion that gallstones are formed as the result of a preceding inflammation of the gall-bladder. Catarrhal cholecystitis leads to the formation of mucus and to excessive exfoliation of epithelial cells. The desquamated cells are responsible for the over-production of cholesterin and bilirubin calcium which form the nidus for the gallstones. The cholecystitis is practically always due to infection, most frequently with the *B. coli;* less frequently with the typhoid bacillus, the influenza bacillus, pneumococcus, or staphylococcus. The suppurative forms of cholecystitis are not followed by the formation of stones. These form during the few months which follow an attack of catarrhal cholecystitis.

The enormous clinical importance of this interval has never been sufficiently recognized. From my own observation, it seems certain that primary catarrhal cholecystitis is an exceedingly frequent disease, but very commonly overlooked. After the attack subsides, if conditions remain favorable, there is a slow formation of gallstones. By therapeutic measures appropriately applied at this stage it is highly probable that the formation of the stones can be prevented.

The prophylaxis of gallstones seems to me an entirely feasible possibility. In the light of modern investigation we are justified in saying that the cholecystitis is the primary disease and the most important factor in producing symptoms; and, furthermore, that gallstones may be considered a frequent though by no means a necessary complication of cholecystitis and only an accidental factor in the symptomatology. Time will not permit of an exhaustive review of the efforts made by surgeons to overcome the evil effects of alcoholic cirrhosis of the liver by Talma's operation; of the occasional cure of hypertrophic biliary cirrhosis by drainage of the gall-bladder; of the relief of chronic dysentery by appendicostomy, and of the occasional total elimination of the colon.

Enough has been brought together in this paper to bear witness to the extraordinary activity within recent years of the workers in all the departments which deal with the abdominal viscera. In many respects our ignorance is still dense. No other part of the body is so pregnant with possibilities. Many of our most obscure problems in metabolism will be solved by the modern chemical and bacteriological methods of study applied to this region. The surgeons must work hand in hand with the internists; these with the chemists, bacteriologists, and experimental physiologists. The closest cooperation possible is desirable. The pure scientists will gain by a clearer appreciation of clinical problems. The clinicians must keep in the most sympathetic touch possible with the results of the laboratory. What could be more appropriate than that there should be joined in one society the workers in these diverse and yet intimately correlated fields, for mutual criticism, discussion, inspiration? If the sciences which deal with the abdominal viscera are to grow under the most favorable conditions possible, then such an association of coworkers becomes an absolute necessity.

The American Gastro-Enterological Association, with a full appreciation of these facts, has gathered into one fold surgeons, internists, physiological chemists, and experimental physiologists, and offers, I believe, the first example in America of a society thus constituted. It invites the cooperation of all those who in a broader or narrower sense are working for a solution of all those problems which are specifically involved in this department of medical science.

THE SEPARATION OF THE URINE OF THE TWO KIDNEYS.

By GEORGES LUYS, M.D.,

PARIS.

Since every individual has two kidneys, it follows that in order to know and appreciate completely their function it is necessary to collect separately the urine of each. It is necessary to separate the urines not only to make the diagnosis of a renal lesion, but also and above all when surgical interference seems to be indicated in order to assure oneself of the integrity of the supposedly healthy kidney. To learn the renal function two methods were formerly employed and seemed to give sufficiently accurate results. These two methods were a weighing of the clinical symptoms and the examination of the total urine of both kidneys. To-day it is admitted, however, that these two methods are altogether insufficient to give us a true idea of the function of the kidneys.

The clinical symptoms may, in some cases, afford sufficient evidence of the existence of disease of the kidney, but more often they are completely silent or lead us into error.

For instance, in a case under my observation all the clinical symptoms indicated a nephrectomy of the right kidney; the woman presented an abundant pyuria with pain and swelling of the right kidney, the left kidney being absolutely painless and insensible. The separation of the urines showed, contrary to all expectation, that all the urinary elimination was done by the right kidney, while the left one recorded practically no urine. The nephrectomy of the left kidney, done some time later, upon the indications furnished by the separation of the urines, showed the complete functional insufficiency of this organ, and the fatal consequences that would have followed an operation based on the clinical indications.*

When we read the report of a surgeon who has performed a nephrectomy and see the patient die twenty-four to forty-eight hours later, recognizing too late either that the patient had only one kidney, or that the one left behind had an insufficient function, we are struck by the thought that the separation of the urines has a vital importance. Finally, clinical symptoms alone can never show surely the integrity of the other kidney, which it is indispensable to know when indications for a nephrectomy are present.

Can we learn the function of each kidney by examination of the mixed urine of the two kidneys? I do not hesitate to affirm the contrary. Although, from a purely medical point of view, it may suffice to decide on the insufficiency of the two kidneys by examination of the total mixed urines, from the surgical point of view, which takes account of unilateral lesions, this method of diagnosis is notably insufficient, and it is upon the study of the urine of each kidney separately that we must base surgical interference.

Among the factors to be taken into account in an examination of the total mixed urine the principal are: urinary quantity, density, chemical composition, cryoscopy, urinary toxicity, and tests of secreting activity.

Among these the quantity and the density of the urine are subject to considerable variation, so that it is impossible to arrive from this study at any precise results.

The chemical composition may lead one to commit grave errors. Indeed it may indicate that renal elimination is insufficient when only one of the kidneys is involved, either because the kidney does not present compensatory hypertrophy, which is frequent, or because this same kidney is affected reflexly in sympathy with the poor function of its diseased fellow.

Again, the chemical composition of the total urine may show that the urinary function is going on normally, when in reality both kidneys are diseased. In this case there may be in both diseased kidneys a certain amount of normal tissue capable of functioning, or there may be in one of them a sufficiently large portion of healthy tissue, or a compensatory hypertrophy.

Cryoscopy, which has for its object to ascertain the quantity of solid substances dissolved in the urine, is subject to several variations when we study the mixed urine of the two kidneys, so that it is impossible to draw correct and important conclusions. It is the same with the toxicity of the urine.

With reference to tests to determine the integrity of the eliminative function, we should recall that such eliminations occur for medicaments as well as for coloring matters. Among these methods the commonest, which was suggested by Achard and Castaigne, is that of the methylene blue test, which consists of injecting under the skin a cubic centimeter of sterilized five per cent. methylene blue solution and collecting the urine every half hour, observing whether it is colored blue. In the normal condition it commences to be blue a half hour after the injection; the coloration increases and is at its maximum of intensity from three to five hours after the injection. It then diminishes slowly, but continues in general for from forty to fifty hours.

In truth none of these methods gives us an exact idea of the unilaterality or bilaterality of renal lesions, and they cannot furnish the surgeon with accurate and useful information. On the other hand, when we examine separately the urine of the right and left kidneys it is practically certain that we can obtain absolutely precise information of the respective function of each kidney.

To learn the function of each kidney it is necessary that the separation of the urine should be made during half an hour, and that the quantity of urine obtained from each kidney should be at least ten cubic centimeters. Indeed, in some conditions of renal retention the ureteral ejaculations are very infrequent, and if we observe for less than that time we are in danger of aiming at false results. It is by a methodical and rational analysis of the products obtained that we may arrive at precise and certain results. The combined volumetric and physicochemical examination of each specimen of urine should be performed with care. The same should be done for the color, appearance, and reaction of each specimen. When these preliminary observations have been made each tube should be centrifuged with care; the precipitate should be put aside for microscopical examination, and the decanted urine will serve for physicochemical examination.

The cryoscopic examination of the separated urines of the two kidneys has a much greater importance than when it is made from the mixed urines of the two kidneys. The conditions of elaboration of the urine are identical for the product of each gland, and it is legitimate to admit that of the two kidneys, the one that functions the best is that which eliminates during a given time the most solids; therefore the cryoscopic examination

*Numerous other cases, absolutely similar to this one, are cited in my work on "Exploration de l'Appareil Urinaire." Paris, Masson, 1907.

of the urine of one side, taken alone, would have no value, but it may furnish valuable indications when compared with that of the opposite side.

It is extremely important to determine the amount of urea, as that will furnish the most precise information in the comparative study of renal elimination. It is the most important point to be studied in separation of the urines of the two kidneys and the safest guide from which to draw deductions. Also the elimination of methylene blue will give important information, aiding us to appreciate the functional condition of the two kidneys. The histological examination of the deposits obtained by centrifugation gives us information regarding the inorganic sediment and the microscopic elements. This histological examination of the precipitates is

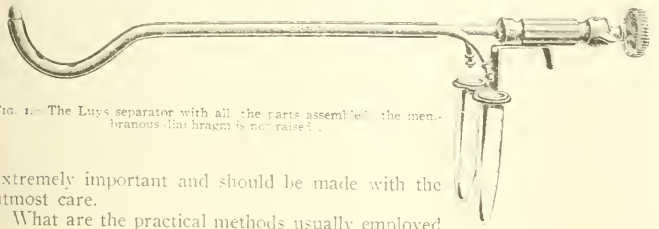

FIG. 1.—The Luys separator with all the parts assembled: the membranous diaphragm is not raised.

extremely important and should be made with the utmost care.

What are the practical methods usually employed to collect the separate urine of the two kidneys? If we look at the various methods used for separation of the urine of the two kidneys we shall see that they are in principle three in number:

1. Ureteral compression, which consists of obstructing for a certain time one ureter and collecting during this time the urine of the other kidney. This method presents a capital defect, which is that of the impossibility of collecting at the same time the urine of the two kidneys. The renal function undergoes from time to time variations, and the important point, which is to establish a comparison between the work done by each kidney, at the same time cannot be obtained. There are in reality only two practical methods for separating the urine of the two kidneys, viz.:

FIG. 2.—The separator with the membrane raised.

2. Ureteral catheterization.
3. Intravesical separation of the urines.

Catheterism of the Ureter.—Although it is certain that from a theoretical point of view the only method that is rigorously exact and absolutely certain for studying the secretions of the two kidneys separately is the simultaneous catheterization of the two ureters obtained during twenty-four consecutive hours, it is not less true that from a practical point of view the thing is not generally possible. Really, to obtain accurate information regarding the functional condition of the kidneys and definite indications for operation, intravesical separation of the urines in the immense majority of the cases is absolutely sufficient, and it has undoubted advantages over the method of ureteral catheterization.

The introduction of a sound into the ureter through its vesical orifice is the only method which will permit of a true exploration of the ureteral canal, whether we wish to examine for strictures, obliterations, or calculus of the ureters, or to explore the pelvis of the kidney to find a calculus, or measure the capacity of the pelvis. We should recall that catheterism of the ureter may be practised for therapeutic ends and that it may enable us to carry out lavage of the pelvis in case of simple pyelitis; but though the employment of the ureteral catheter is absolutely indicated in the exploration of the ureter and pelvis of the kidney, the field of this method of investigation of renal function seems to be limited.

The principal objections to the method of ureteral catheterization are:

1. Infection.—The ureteral sound introduced by means of a cystoscope in a bladder infected and full of liquid may, in traversing this septic medium, carry into the pelvis of the kidney pathogenic germs which will produce infection of the kidney itself. This is a fact that is undeniable and certain, and the accident may occur in spite of numberless precautions, including repeated lavage of the bladder. The ureteral sound, reaching an infected bladder, picks up pathogenic germs, not only on its external surface, but also, which is more important, in its cavity. The sound thus soiled with impurities internally and externally becomes a carrier of microbes, susceptible of secondarily infecting the pelvis of the kidney. This fact has been confirmed by a typical case reported by Rafin of Lyon, who found in one case spermatozoids evacuated from a ureteral sound in place in the ureter. The answer to this capital objection of the danger of infection has been made by reserving catheterism for kidneys supposed to be infected already, while the urine from the sound kidney is allowed to collect at the same time in the bladder, flowing directly from the ureter; but the clinical symptoms on which we must base the knowledge of which is the diseased side are often completely at fault, and we may be exposed to the danger of catheterizing a healthy ureter and causing the patient to run the risks of infection.

2. Untrustworthiness.—The method of ureteral catheterization may produce error in five different ways:

(*a*) Since it is impossible to be certain that the caliber of the sound is adapted to the size of the ureter, it results that a little urine may filter out around the sides of the catheter and become mixed with that of the other kidney which runs directly into the bladder, which will give false results.

(*b*) The passage of the sound into the ureter may cause lesions and make the ureter bleed, which will cause the belief that a hematuria exists.

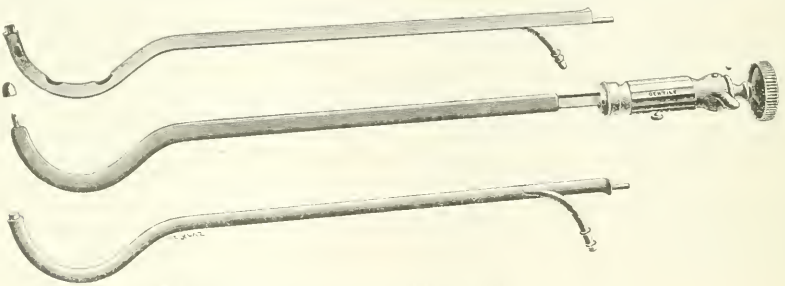
(*c*) Since we must catheterize only the infected ureter and collect the healthy urine in the bladder, the urine of the supposedly healthy kidney will reach the bladder without infection; but there it becomes mixed with the pus contained in the bladder, and the impossibility can be seen of knowing whether the morbid elements belong to the bladder or the supposedly healthy kidney.

(*d*) The fourth cause of error consists in the fact that we cannot ever be absolutely sure that with a prism-cystoscope the ureteral sound has been passed into the ureter, and that it has not slipped aside from the orifice at the moment when the cystoscope was removed.

(*c*) Finally, the fifth cause of error is the abnormal excitation of the kidney which is produced, a fact which has been brought to light by Franck of Berlin.*

3. Difficulties.—The difficulties of the method of ureteral catheterization are of two kinds. Some come from the operator, for it is certain that a long apprenticeship is necessary in order correctly to make a ureteral catheterization. Others come from the patient, for catheterism is often absolutely impossible to perform, either because of intolerance of the bladder or because of pyuria or hematuria, which would render a view of the orifice of the ureter impossible.

Separation of the Urine Within the Bladder.—The endovesical separation of the urine obviates all these objections. It consists in collecting in the bladder at the level of the orifice of the ureter the urine of each kidney. The apparatus most commonly employed is represented in the accompanying illustration. Recently brought forward, this method, which had fallen into oblivion abroad, was unknown in France before I introduced it. Six years of study and patient research have demonstrated that the essential principle which has guided me since the beginning is the expression of a truth. It is well known how widely the method has been used and how much interest it has excited not only in France, but also abroad.



—The separator dismounted, showing the three parts of which it is composed.

The points of superiority of the endovesical separation of urine over separation by the ureteral catheter are many; we will mention the principal ones. In the first place, the endovesical separation of the urine is a simpler method and may be employed by any surgeon who is accustomed to urinary procedures, while ureteral catheterism can be used by only a small number of specialists. Next, the separation of urine by the endovesical method is absolutely exempt from the dangers of ureteral catheterism, and can never, like that method, expose the patient to the contamination of a previously healthy kidney, by a ureteral sound passing through an infected medium. Again, in bladders containing morbid urine, when hematuria or pyuria renders the view of the ureters difficult, the intravesical separation of the urine is superior to catheterization.

Again, endovesical separation shows immediately the diseased kidney when, as frequently happens, no clinical sign has led us to suspect one kidney more than the other. Endovesical separation of the urine may be made with a contracted bladder. A special model of separator is made for separation in children. The smallness of the passages in children has prevented the utilization of the cystoscope in many cases. Finally, endovesical separation of the urine does not affect the function of the kidney, or, if it affects it, its action is equally upon the two kidneys, while catheterism of the ureter produces excitation only of the kidney manipulated.

It is not less true that the method of intravesical separation of the urine is susceptible of criticisms, and these may be summed up as follows:

In the first place, the endovesical separation of the urine does not furnish a pure renal urine, for the urine is mixed with the product of the bladder which it traverses. Nevertheless, in an analysis of the separated urines we need take account of only one small factor, viz., the presence of bacteria or of blood. There are other elements, such as the volume of urine, the dosage of urea, the cryoscopic point, which preserve their original value in this method and may serve as elements of great value in considering the function of the kidneys. The histological examination of the sediment obtained by the separation is also extremely important. From the bacteriological point of view the intravesical separation of the urine may furnish information that is not absolutely precise, for there may often exist lesions in the bladder associated with those of the kidney—for instance, a left renal tuberculosis with tuberculous ulcerations of the right side of the bladder. It is in such conditions that it is necessary to combine endovesical separation with simple cystoscopy to ascertain the condition of the bladder or of the ureteral orifices, or the existence of ulcerations of the bladder; perhaps even catheterization of the ureters may be necessary to collect the urine coming from the kidney without contamination in the bladder.

The second criticism that can be made of the method is that the application of the separator cannot be continued for so long a time as that of the ureteral catheter. But it is quite certain that in one-half to three-quarters of an hour the separator will obtain specimens of urine that will furnish sufficient elements to enable us to determine the function of the kidneys.

Lastly, it has been objected that it is impossible to diagnose a renal retention. Although there is a certain amount of truth in this statement, it is not absolutely correct. If in the course of the application of the separator it is seen that no urine is flowing from one kidney, it is always easy to have this organ raised toward the diaphragm by an assistant; it will soon be seen, in response to this procedure, that the corresponding tube fills with a clear liquid in the case of hydronephrosis, and with purulent liquid when there is a pyonephrosis with retention in the pelvis. This maneuver succeeds in every case in which the caliber of the ureter is normal and it is not fixed by pathological adhesions. It fails,

*Franck: Verhandlungen der Deutschen Gesellschaft fur Chirurgie, Thirty fourth Congress, Berlin, 26-29 April, 1905, S. 72-74.

on the other hand, when the ureter is fixed by adhesions or is strictured. In the latter case a sound introduced into the urethra will be arrested at the stricture and will give us more definite information regarding the presence or absence of renal retention.

In conclusion, we may say that it is not just to regard these methods as rivals in the separation of the urine. Each of them has its indications and its well-determined rôle. The separator, more simple in employment and exempt from danger, may be employed in many more cases than ureteral catheterism. Well applied it gives results that are exact and certain, but in certain cases other diagnostic methods are needed either to collect urine directly from the kidney without contamination in the bladder, or when it is desired to explore the pelvis of the kidney. In this case ureteral catheterism will find its application. When this exploration is judged necessary it will be of great advantage to practise it with a direct-vision cystoscope, for in this case the chance of renal infection will be reduced to a minimum.

To sum up, the endovesical separation of the urine has the following advantages over ureteral catheterization: (1) It is more simple; (2) it may be applied in more cases than ureteral catheterization; (3) it is devoid of danger; (4) the information given by the separator, when properly applied, if possibly not better is at least as exact as that furnished by ureteral catheterization.

20 Rue de Grenelle

PRIMARY DYSMENORRHEA.*

By MAUDE GLASGOW, M.D.,

NEW YORK.

The function of menstruation is not peculiar to the human female, but in animals the discharge is of mucus only, and among human beings the lower the scale of intellect the greater the relative quantity of mucus to that of blood. Ovulation, though usually occurring with menstruation, is not necessarily coincident with it. The act of menstruation affects the body and its functions markedly. The elimination of urea is decreased at this time, although during the preceding week it is increased. Arterial tension is higher, remaining so for a few days, when it gradually falls. The temperature is about a degree above normal, especially during the third or fourth day of the period.

Weir Mitchell has observed a loss of weight, with gain between the periods, and Ewing has found the hemoglobin reduced from 4 per cent. to 15 per cent., with some leucocytosis.

Headache is quite frequently present, the breasts occasionaly swell, and the thyroid gland often enlarges; there is greater susceptibility to cold; there may also be local discomfort and diarrhea. Reflex phenomena are observed in the skin, erythemas, acne, eczema, and other eruptions appearing or being aggravated as the period approaches.

Riebold is of the opinion that the occasional menstrual fever is caused by absorbed toxins or decomposition products which also produce the dermatological and nervous symptoms, and that rheumatic affections, including heart disease, may be induced by infection from the genital tract during menstruation. The chemical products which produce these changes in the organism are supposed to be due to superfluous substances finding their way back to the genital organs to be eliminated; but when not so disposed of they are again taken up by the body, on which they now exercise a toxic influence.

Gebhard of Berlin has demonstrated the fact that during the period there is no shedding of surface epithelium; that there is first a premenstrual congestion, with small collections of blood under the surface epithelium, which, with increasing pressure, passes out between the epithelial cells, occasionally breaking off small fragments. As blood pressure decreases, hemorrhage becomes less profuse, and finally ceases.

The menstrual cycle as given by Leopold is as follows: Tumefaction of mucosa, five days; flow, four days; regeneration of mucosa, seven days; resting period, twelve days.

Fluger's theory that menstrual bleeding and partial denudation occur in order to afford a freshened surface for the ovum to rest upon is now generally accepted, though we still remain ignorant of its evolution. We hear so much of the pathological aspect of menstruation that we are apt to forget that it is a normal physiological process, and should not, therefore, be attended by severe pain; and, indeed, in some normal cases, the week preceding that of menstruation is one of increased vigor, while there is present during the period a condition of well being and buoyancy, with greater energy and capacity for work. This, and the greater elimination of urea, imply an increased nutrition which seems but natural to expect when the soil is being prepared for the growth of a new being.

Painful menstruation seems to have increased with the march of civilization. Among primitive people we do not find the exercise of the function producing much, if any, inconvenience, while among the country girls of Great Britain and the continent of Europe, who have an abundance of fresh air, exercise, and plain, wholesome food, there is but little discomfort or suffering at the physiological period. In all our large cities, however, both in this country and abroad, the majority of women suffer more or less, usually more. Not only the city-bred woman, but girls brought up in the country and who have menstruated painlessly for years, will, many of them, when subjected to the depreciating conditions of city life, experience discomfort and pain at the epoch, and this, too, without any pathological condition of the pelvic organs to account for the change. Englewood, who in 1900 investigated the subject of dysmenorrhea, found among American girls that from 50 per cent. to 80 per cent. suffered from painful periods, and Maria Tobler, who made similar investigations among German women, including all classes of society, found 84 per cent. suffering from either pain or disability, and at the same time found that there was present a lessened vitality and impairment of energy. This frequently occurring periodicity covering so many years, and affecting the health, strength, and wage-earning capacity of those affected, becomes a serious matter to the sufferers as well as their friends.

When we know that dysmenorrhea is to a certain extent preventable, it seems strange that its burden of suffering should continue to affect womankind and to increase with advancing knowledge. Women have been taught to regard their periodical pain as a natural phenomenon, and adopt merely palliative remedies as suggested by their friends, or prescribed by a physician, while but little thought is given to underlying conditions. We usually find the causes of dysmenorrhea systemic or local. Some cases seem dependent on a neurotic temperament, and some on diathesis, pain manifesting itself coincidently with the presence of such diseases as gout or rheumatism

*Read at a meeting of the Cornell Medical Alumni Society, April, 1906.

in other parts of the body, and yielding to treatment appropriate to those conditions. Very many cases are due to a lowered vitality, the result of a debilitated nervous system, and caused perhaps by overwork, insufficient sleep, worry, food which is not nutritious, or insufficient in quantity, lack of fresh air and outdoor exercise.

In numerous cases, however, the primary cause is poor muscular development of the uterus, which painfully performs the function which the well-nourished muscular organ performs painlessly and with but slight effort.

The uterus is lacking in strength and tone, as well as size, until the approach of puberty, when the walls of the young organ develop, becoming under favorable conditions strong and thick. Any influence which interferes with the maturing processes of nature at this time, such as insufficient or poor food, insufficient sleep, excessive mental or physical effort, will check or retard the development of the genital organs, either through defective nutrition, when the whole body suffers, or by deflecting the blood stream necessary for the perfect development of these organs, to other parts of the body.

We know that if a mature woman leads a sedentary life, or exercises her brain actively without taking sufficient physical exercise to counteract the effect of mental effort, she is apt to suffer from amenorrhea, and it has been observed that male athletes usually possess poorly developed sexual organs, while the other parts of their body may be enormously developed. If, then, the functions of the mature genital organs are so easily interfered with, we can readily understand why the lack of care in childhood and early youth can affect the future life of the individual. As the female genital organs are more highly organized and more complex than those of the male, they are more susceptible to adverse influences both during and after development.

Young girls at school or college, who are closely confined and mentally active a good part of their time, who have an insufficient amount of fresh air and exercise, are very apt to suffer from a disordered menstrual function, with which overstudy is usually credited; whereas, mental effort has been but one of several factors which have contributed to the disorder, the dissipation of late hours, with its attendant nervous excitement, insufficient rest, and sleep, and an inadequate amount of fresh air and of outdoor exercise being quite as much to blame. Mental work, combined with judicious exercise, fresh air, plenty of sleep, with due attention to hygienic laws, is not likely to injure anyone with a normal constitution. Miss Fawcett, daughter of the blind postmaster-general of England, who won the senior wranglership by 400 points over the best man in Cambridge University, was not injured in any way by her hard study, but she spent from two to three hours every day in outdoor exercise.

Another class of city girls whom we find frequently suffering from dysmenorrhea includes the anemic young women who labor in shop, office, and workroom. Their disability is mainly due to the adverse conditions which surround them. They enjoy but a minimum amount of fresh air and sunlight. Some are on their feet all day, and others are obliged to sit nearly all the time. Their outdoor exercise is seldom more than a walk to the nearest car, while their slender salaries compel them to board where they can obtain meals cheaply, no matter if they are unappetizing and innutritious. And so they suffer from dysmenorrhea, not from overworking their brains, but because of a poorly nourished body and a nervous system, manifesting its weakness by pain and discomfort in delicate and susceptible structures. For many years the teaching prevailed that dysmenorrhea in nulliparæ was mainly due to anteflexion, and the theories advanced to explain the cause of the pain are interesting. One authority believes that the flexion produces a mechanical obstacle to the flow, resulting in the formation of clots and painful contractions until the clots are expelled. Others attribute the condition to the obstruction of the venous circulation, causing pressure on the nerves at the point of flexure. Others contend that the pain is caused by spasm of the circular fibers of the internal os. Many are of the opinion that the condition is due to the imperfect development of the uterus, or that it may be due to an underlying systemic condition producing an irritability of the pelvic nerves. An English authority claims that dysmenorrhea is just as frequent in straight as in anteflexed uteri, and that pain is as often absent from the latter as present.

Intermenstrual pain has been attributed to sclerotic ovaries, to ripening follicles, and recently to a pelvic neuralgia. The anteflexed uterus we find in dysmenorrhea is usually of small volume; the cervix is long and conical, and the flexure is characterized by its immobility. A uterus of this type is not a well-developed one. Any influence tending to weaken the uterine tissue will produce a flexure owing to lack of muscular tone, although it may also be produced by a fall or blow, by fibroid growths, by endometritis, and even by fecal accumulations in the rectum. In long standing cases of dysmenorrhea we are likely to find an endometritis, due probably to poor drainage, the inflammation perhaps extending to the tubes and ovaries. The external os may be eroded and the leucorrheal discharge more or less profuse.

As these are the days of prophylaxis, and it is easier to prevent than to cure, the prevention of dysmenorrhea should begin in childhood by endeavoring to build up a sound body and a nervous system which can stand the "shocks of time and chance." The child and young adult should have nutritious, unstimulating diet, abundant sleep, especially if of nervous temperament, fresh air night and day, and what is of transcendent importance, judicious daily exercise either out of doors or in a gymnasium. The child is now building up her nervous and muscular structures, and well regulated exercise will develop all the parts of the body, internal as well as external, bringing fresh blood to all organs, and giving strength and tone to the whole body.

While the young woman during the period should be advised not to make any unusual physical or mental effort beyond her accustomed activity, she is in most cases quite equal to the performance of her daily tasks. The constant calling attention to the activities of the organs of generation does not seem wise, although the young woman's guardians should see that she is properly instructed on all physiological matters relating to her future welfare. When the pain or discomfort is excessive it is wise for the patient to remain in bed while it continues severe, adopting preventive measures during the intermenstrual period.

Anemic girls who are leading lives of close confinement will be greatly benefited by spending an hour or two every day in outdoor exercise, and this they can themselves arrange by a little self-denial, perhaps, especially during the summer months. After forming the habit of daily outdoor exercise, and observing care as to diet, patients are often

amazed at the improvement in their symptoms. It is a wise precaution to empty the bowels thoroughly before the expected period, as it often materially decreases the pain. During the period hot drinks and the application of external heat are of benefit; a hot sitz bath will add greatly to the patient's comfort, and a few small and repeated doses of phenacetin. During the intermenstrual period the patient should take hot douches twice a day, avoiding colds, and keeping the feet warm and dry. Daily exercise, nutritious food, faradism when indicated, and tonics to build up the constitution are necessary. Some cases are benefited by dilatation and curettage, but not all by any means, and it is best to employ medical means with the hope of benefiting the patient before resorting to harsher measures.

Hydrastis combined with nux vomica has rendered me good service in very many cases, the only drawback being the fact that it must be continued for a lengthened period, usually two or three months, and that it has a disagreeable taste. There are now other remedies on the market containing hydrastis and also viburnum, which are not unattractive to the eye and not disagreeable to the taste.. Some patients object to taking such drugs indefinitely, and for such apiol, 5 minims, in capsule, three times a day during the week preceding menstruation, will be acceptable; or tincture of pulsatilla in 5-drop doses, three times a day during the week before the expected period, will be found useful. In all cases the patient should keep the skin and other eliminative organs active, should avoid colds, have daily outdoor exercise, and endeavor to keep the nervous and other systems in healthy condition by wholesome, nutritious food and tonics when necessary.

110 East Eighty-first Street.

THE EYE SYMPTOMS OF SPORADIC TRICHINOSIS, WITH REPORT OF CASES.*

By Frank Judson Parker, M.D.,

New York.

Assistant Surgeon Manhattan Eye, Ear, and Throat Hospital; Attending Ophthalmic Surgeon to the Presbyterian Hospital, Out-Patient Department; Consulting Ophthalmologist to Seton Hospital; Consulting Ophthalmologist to the Greenwich Hospital, Connecticut.

Our knowledge of this interesting disease dates from the publication by Zenker of Dresden of his famous theory of the parasite as a pathological factor in human beings. In performing an autopsy on a nineteen-year-old girl who had entered the hospital and died, supposedly of this disease, he found numerous trichinæ in the intestinal tract and in the muscles; the intestinal lesions of typhoid fever were absent. A few weeks before, the girl had been taken sick after eating pork, the source of which was traced and numerous other cases discovered. Hardly had this case been reported than reports of epidemics came from North Germany. Previous to this date there had been numerous reports of the finding of the parasite at human autopsies. In London, Peacock, in 1828, and Hilton, in 1833, had found encapsulated trichinæ in the muscles of man; Paget, in 1835, found them in an Italian who had died of tuberculosis, and recognized them as the entozoa which Owen had described as *Trichina spiralis*.

Leidy of Philadelphia, in 1847, found it in the hog; this opened the way for Zenker's classic work. Kirchenmeister and Virchow, in 1850, by a long series of experiments, showed that the trichinellæ became adult in the intestine a few days after the entrance of the larvæ, and that the females were viviparous. Previous to this time they had been regarded as harmless guests of man. Soon after introduction into the intestine, the encysted trichinæ escape from their capsules, which are destroyed by the gastric juice; they then enter the duodenum and jejunum, where they become adult copulation taking place in two days; the males die and the females bore deeply into the villi or through Lieberkühn's glands, penetrate into the mucous membrane, and thus reach the lymphatic spaces, here depositing their young. The newly born larvæ measure about one millimeter in length. These larvæ are carried by the lymph stream, or the blood, and are distributed throughout the body. The conditions necessary for their further development are found only in the transverse striated muscular system. On the ninth or tenth day after infection the first trichinæ have reached their destination and further invasions are constantly taking place, because the intestinal trichinæ live from five to seven weeks and continue to reproduce. It is the invasion of the muscles by the migration of the new brood which causes the inflammation manifested by severe pain, fever, and edema about the eyes. The trichinæ in the encysted condition remain alive and capable of development for many years, the subsequent invasions producing more severe symptoms.

The Germans have been the greatest sufferers from this disease, and a report from their Bureau of Animal Industry from 1860 to 1898 gave 14,820 cases, with a mortality of 835. Their careful inspection of pork has greatly reduced the number of cases, and up to 1898 no case in Germany had been traced to American pork products. One of the most glaring disclosures of the recent food investigation was the fact that there was no inspection for trichinosis in hogs intended for sale in this country, a microscopic inspection being maintained solely for the benefit of Europe, and pork that was found unfit for exportation was being sold for food in this country. Trichinosis in man has been considered a rare disease in this country, only nine hundred cases being reported since 1868. That the disease is far more prevalent here than has been suspected is proven by H. U. Williams, who reported in 1901 that out of 505 autopsies of persons in whom the disease had not been suspected during life 5.34 per cent. had trichinosis. In 1897 a case in Dr. Osler's clinic with suspected typhoid fever, was found to have a leucocytosis with increase of eosinophile blood cells. Examination of muscle tissue showed numerous trichinæ, and further examination showed the blood examination to be of the greatest diagnostic importance in recognizing this obscure disease. Osler has reported seven cases of trichinosis, all of whom showed a marked leucocytosis and eosinophilia. Cabot regards this as a constant symptom, and states that it has reduced trichinosis to the list of diseases which are easy of diagnosis. Ewing, on the other hand, states that while increased eosinophile should always suggest trichinosis, this has long been known to accompany other conditions. Of thirty-seven cases reported up to 1903 thirty-one had eosinophile from 20 per cent. to 86 per cent., and there was no relation between the amount and the severity of the case. The eosinophilia varies to a great extent from day to day. Vickery reported a case that one day showed 23 per cent. and two days later 2 per cent., and in the following two days 37 per cent.; it also continues high long after recovery.

*Read before the Section of Ophthalmology, New York Academy of Medicine, October 15, 1906.

There are a large number of diseases in which an increase of the eosinophiles takes place, usually with a small percentage, but the condition most likely to be confused with trichinosis are the other intestinal parasites. A differential diagnosis presents little difficulty with their exception. Packard, in reporting a case in 1897, speaks of the marked edema of the eyelids and surrounding skin, especially above the brow; this subsided after three or four days; there was no involvement of the conjunctiva. The same year Oliver reported the eye examination of a case reported by Brown as follows: "Vision and accommodation normal; pupils equal, and respond freely to light and accommodation; marked hyperphoria for near and far; fundus normal, except a small striated hemorrhage overlying the interior temporal vein just beyond the primary bifurcation in the left eye; fields normal; the only gross occular change being the disturbance in the muscular equilibrium in the vertical meridian."

Osler reported five cases in which there was edema of the eyelids, and he considers this as being one of the three characteristic symptoms—the other two being leucocytosis with eosinophilia, and the muscular pain and swelling.

Dr. David Bovaird, Jr., in a recent report of ten cases of sporadic trichinosis at the Presbyterian Hospital, noted the marked edema of the eyelids in nine of them; in three it was the earliest symptom. Five had hyperemia of the conjunctiva, and one case had a mucopurulent discharge. He regards the edema as one of the most characteristic symptoms.

The following five cases, to which I ask your attention, came under my observation at the Presbyterian Hospital in the spring of 1906:

Case I.—Miss C. K., a trained nurse, aged thirty; single; consulted me on January 5, 1906; was of German parentage; lived in New York since seven years of age; general condition excellent; family history negative; had frontal headache after use of eyes. I ordered a correction of plus spherocylinders to be worn constantly. Her eye muscles were normal. I saw her again on January 25, and she had been free from the headache since wearing the glasses. I next saw her on February 13 following. She had marked collateral edema; tenderness of the globes; diplopia on looking down, and occasional attacks of nausea. Examination showed vision 20/20 each eye with correction (homonymous diplopia with red glass); right hyperphoria, 1½°; esophoria, 2°; continual headache and muscular pain. This continued with increased severity, and on February 23 she was admitted to the Presbyterian Hospital on Dr. James' service. Blood count showed an eosinophile of 20 per cent.; collateral edema, ocular conjunctiva injected, eyes tender to the touch and painful on rotation; pupils reacted to light and accommodation. The diagnosis of trichinosis was confirmed by sections of lumbar muscles, showing the characteristic interstitial myositis. Discharged from hospital on April 5. I last saw this case on May 22. She had been free from headaches and her eye muscles were normal.

Case II. Miss M. W., age 25; admitted to Presbyterian Hospital on January 19, 1906; a domestic; general condition good. Four days ago was taken with severe pain in both eyes; pain increased on rotation. The following evening the eyelids began to swell and face was flushed; following morning the lids were closed from the increased swelling, both eyes very red and painful; had no muscular pain until two days following the pain in eyes. On admission to the hospital eyelids were swollen; slight edema of the conjunctiva; subconjunctival ecchymosis of the lower half of each eye; eyes very sensitive to touch and painful on rotation. Blood examination showed 30 per cent. of eosinophiles; this was 49 per cent. on January 27 and 52 per cent. on February 7. Section from gastrocnemius muscle showed trichinæ. February 13 symptoms had disappeared except slight headache. Patient discharged.

Case III.—W. B., German; aged 44; admitted to hospital May 30, 1906. One month ago had severe abdominal cramps, vomited frequently; pain and anorexia continued. Eight days ago noticed puffiness of eyelids; a steady pain seemed to be in back of eyes; rotation in any direction caused severe pain. Two days ago had pain in throat and hoarseness. On admission eyelids were swollen, ocular conjunctiva injected, globes painful on pressure and rotation. Blood examination showed an eosinophilia of 18 per cent. Section of muscle from leg showed large numbers of encapsulated trichinæ.

Case IV.—Miss V. B., aged 8; a child of patient III. Was admitted to hospital on May 30, 1906. Three days ago had slight headache, lassitude, and swelling of eyelids; no gastrointestinal symptoms or muscular pain. On admission had marked swelling of lids, conjunctival injection; no muscle tenderness or pain on motion at any time; eosinophiles, 35 per cent.

Case V.—Mrs. M. B., German aged 25; admitted to hospital May 30, 1906. A large, well-nourished woman. Seven days ago had distressing pains in legs and back; had swelling of the eyelids and severe pain in head and eyes. On admission had injection of the ocular conjunctiva, tenderness, and painful rotation; blood examination showed an eosinophile of 18 per cent.; urine contained no albumin and a few epithelial casts. On June 2 ophthalmoscopic examination showed beginning optic neuritis in each eye; veins enlarged. On June 7 there was a marked optic neuritis, with edema of the retina in each eye; veins large and tortuous, arteries small, a small hemorrhage just above the macula in the left eye. The urine showed a faint trace of albumin and a few granular casts and pus cells. On June 14 the retinal edema and neuritis was less, several small hemorrhages in the superior temporal field of the left eye; no hemorrhages in the right eye. Condition of the urine same as on the 7th. This patient improved steadily and was discharged on the 27th of June. The optic neuritis had disappeared, and there were only slight traces of the hemorrhages. The fundus lesion in this case was characteristic of acute nephritis, which was probably caused by the intestinal toxemia.

Case VI.—A. D., a school girl; Italian; admitted to hospital on March 20, 1906. Twelve days ago was taken with severe pain in the muscles and swelling of the eyelids; on admission to the hospital she had collateral edema with injection of the ocular conjunctiva. Blood examination showed an eosinophile of 18 per cent. Section of muscle from calf of leg showed immense number of trichinæ and myositis.

The incubation period in these cases was from one to two weeks, which is the time required for the immature parasites of the infected meat to reach maturity and reproduce their embryo, and for the embryo to leave the intestinal tract and invade the muscles. The invasion is marked by a variety of symptoms, such as loss of appetite, exhaustion, fever, headache, abdominal pain, vomiting, muscular pain and tenderness, swelling of the eyelids, and

pain on pressure and rotation, eruption on the chest and back. In summing up the eye symptoms in my six cases, all had collateral edema, and in four it was associated with conjunctival hyperemia; four had tenderness of the globes and pain on rotation; one had subconjunctival ecchymosis; one case showed diplopia as the earliest symptom; one case had acute nephritis, with neuroretinitis and hemorrhages.

Various explanations have been given for the edema, such as blocking of the lymphatics by the parasites; others, by pressure on the blood-vessels. Bovaird's theory, which seems the most rational, is that the edema is simply an attendant feature of the myositis, which is most noticeable about the eyelids, where serous effusions most readily appear. Microscopic examination of the muscle shows an interstitial myositis, the exudate consisting of small round cells lying in the endomysium and perimysium. A microscopic section of the skin lesion in one of Dr. Bovaird's cases showed engorged subcutaneous capillaries and a serious exudate.

In reporting these cases I have omitted much of the history that might be of interest, and have endeavored to emphasize the eye symptoms as being of especial importance—four of these six patients having sought professional aid on that account. Failure to find the trichinæ in the muscle sections should not mean a negative diagnosis; a case may present the characteristic clinical picture before the trichinæ have developed in sufficient number to be easily discovered.

The important points on which the diagnosis depends are: (1) Muscular pain and tenderness, due to general myositis. (2) Fever resembling that of typhoid. (3) Leucocytosis ranging from ten to twenty thousand. (4) Eosinophilia from 10 to 70 per cent. (5) Edema of the eyelids, with tenderness of the globe and painful rotation. (6) Finding of the trichinæ, or the inflammatory areas between the muscle fibers.

I have gone more into the general symptoms than my subject would suggest, my purpose being to give briefly the points of diagnostic importance, for I believe that the ophthalmologist is the one most liable to be consulted first by these patients, and I would urge the importance of excluding trichinosis before making a diagnosis of muscular rheumatism, orbital cellulitis, or adenitis of the lacrymal glands.

VENEREAL PROPHYLAXIS—A PROBLEM IN SOCIAL HYGIENE *

By ROSWELL S. WILCOX, M.D.,

PROVIDENCE, R. I.

"SOCIAL sentiment holds that it is a greater violation of the proprieties of life publicly to mention venereal disease than privately to contract it." (Morrow.) But when that sentiment is founded upon and fostered by deepest ignorance on those matters of health, vital alike to the individual and the race, then I for one must disregard such settled opinions of bygone ages.

Mortal mind can conceive of no nobler work than that of preventing disease, physical, mental, or moral. A casual survey of the history of medicine reveals numerous laurels won on the preventive field; vaccine has dissipated the former fear of smallpox; antitoxin the dread of diphtheria; fresh air in abundance, combined with nutritious food and well-regulated exercise, are reducing the morbidity and mortality from tuberculosis; the introduction of asepsis and antisepsis into the domains of surgery and obstetrics has vastly broadened these special branches of the physician's art, and converted the unknown and hazardous into the familiar and comparatively safe procedures of the present day.

With the passing of years one class alone, among the various infectious diseases, seems to have been almost entirely neglected. Founded upon human frailty and ignorance of the sexual self, and patriarchial as life itself, venereal diseases are still shrouded in mystery and propagated by ignorance—ignorance on those vital matters of sexual hygiene and physiology which in itself is a sad reflection on this supposedly enlightened age.

In using the general term venereal, I refer to that class of diseases usually, but not always, contracted from sexual intercourse, and comprising the three affections commonly known as syphilis or "pox," gonorrhea or "clap," and chancroid or "soft chancre." Syphilis might be defined as a specific eruptive fever "diluted by time," characterized by a primary sore or chancre and followed by constitutional symptoms. It must certainly is, as the laity express it, "in the blood." Gonorrhea, on the other hand, is usually a local contagious disease, a specific inflammation of the urethra caused by the gonococcus of Neisser, and characterized by a discharge of pus or mucopus from the urinary meatus. Because it is so frequently acquired during sexual intercourse, and on account of the disastrous results following in its wake, it is now regarded as the "most venereal of all venereal diseases." (Keyes.) Chancroid, or soft chancre, is a localized ulcer, usually occurring about the genitals, resembling in many respects the hard sore of syphilis, but never followed by the protean manifestations of that terrible disease.

Venereal diseases prevail among all peoples, occur at all ages, and recognize neither color, creed, nor sex. Innocent and guilty, rich and poor, young and old, alike suffer from the ravages of these loathsome diseases. Innocent childhood is no barrier against the affliction, since syphilis, most noticeable among all diseases, passes on its hereditary taint unto the

*Read before the Lister Club, Providence, Wednesday evening, February 20, 1907.

third and fourth generations, and in forms curiously diverse, often writ large and indelible and always sad to contemplate. Ecclesiastical robes are not always proof against the temptations of the seducer's art and should not mislead us into exonerating their wearer when other evidence is strongly suspicious of wrongdoing. Tothergill well expressed this thought in his classical quotation, "a ham-colored eruption and a serpiginous ulceration are not incompatible with a bishop's mitre."

Age must be a factor of some importance, since statistics show that 75 per cent. of all infections in public women occur before the twentieth year, and 25 per cent. of all infections in men are contracted before they become of age. Commenting on these figures, Morrow says: "This is the age when the centers of arrest, as they are termed—judgment, reflection, and will—are not developed, an age when the individual is influenced by impulse, imagination, and curiosity." Those of the psalmist's span of three score years and ten cannot claim exemption, for the fruits of their youthful indiscretions may appear in due season, but generally under assumed names. From middle life and onwards grim disease reaps a bountiful harvest and the enormous debt created by venereal infection in earlier years is often erroneously charged to the account of some degenerating disease. But he who is able to read between the lines may commonly, from a study of the symptoms or pathology, discern as the essential causative factor a gonorrhea or syphilis of former years. Whatever mild and noncompromising term our elastic medical nomenclature may attach to the sequelæ of venereal disease, be it tabes, paresis, aneurysm, or other name, it is a patent fact that the law of penalties is exacting its wages, and we are witnessing the fulfillment of that prophecy:

"The sins ye do by two and two
Ye shall pay for one by one."

Statistics on venereal diseases are notoriously unreliable, in part due to privacy being the distinctive peculiarity of this class of infections, and largely because of the incomplete or utter lack of official returns on sexual diseases from our boards of health. And until that day when physicians shall be compelled by law to report all such diseases to their respective boards of health we shall be dependent upon the educated guesses of specialists for all comparative and working data pertaining to the venereal peril. From such competent, though incomplete sources, we obtain the following facts: Venereal diseases have the odious distinction of being second on the list of epidemic contagious diseases responsible for a large individual proportion of deaths of the human race, tuberculosis being first. (Spencer.) Morrow estimates that one-eighth of all patients in the New York hospitals suffer from venereal diseases, or their consequences, and the number is gradually increasing. The same authority claims that 60-80 per cent. of stillbirths are the result of syphilis, while of all involuntary sterile marriages 30-35 per cent. are due to gonorrhea. Venereal diseases and criminal abortion are ranked first rivals in their causation of race suicide. Fournier claims that one-seventh of the population of Paris is syphilitic. Among the more than 225,000 syphilitics in New York City 50-85 per cent. among the female ones are believed to have been innocently acquired. If anything in the practice of medicine has forcibly impressed me it has been the ignorance, the frailty, the indifference of our young men to the dangers of gonorrhea.

Neisser, whose name the specific germ bears, estimates that 80 per cent. of adult males have at some time had gonorrhea, and ranks it next to measles in its widespread prevalence, while Bransford Lewis ranks it far above syphilis as a direct cause of death. Those who are inclined to regard this disease in the light of a trivial ailment should ponder the following facts: (1) Of all miscarriages at or before the third month three-fourths are due to a latent gonorrhea in the male. (2) Our blind asylums report 20 per cent. of their inmates as sufferers from the effects of gonorrheal infection of the new-born. "In Germany there are today some 30,000 blind as a result of gonorrheal ophthalmia." (3) Of all cases coming into the hands of the gynecologist one-eighth are due to gonorrhea; and of all deaths from diseases peculiar to women some 80 per cent. are believed to result from the same cause. "Gonorrhea produces its fearful wounds in the young households of to-day; syphilis silently deteriorates generation after generation."

The foregoing statistics, faulty and incomplete and inconclusive as figures are, have impressed us all, I believe, with the truth of Dr. Morrow's dictum that "the chief social danger of venereal diseases comes from their destructive effects on the health and productive energy of the family."

The specific cause of gonorrhea is infection with the microscopic, vegetable parasite, the gonococcus of Neisser, acquired from any person having the disease by the mere contact of the discharge or "leakage" with healthy urethral mucous membrane of the indiscreet. Unlike syphilis, this disease is largely local in its action and is most frequently contracted by sexual commerce, legitimate though such intercourse may be. The specific germ producing syphilis has until quite recent date been a debatable question, but is now believed to be a spiral-shaped animal microorganism, the *Spirochæta pallida*, which gains entrance into the system through some abrasion of the skin or mucous membrane; is taken into the blood current and from there the poison may be conveyed to any part or organ of the body, brain, heart, liver, bones, nerves, or elsewhere, producing, besides the primary local "sore" general constitutional symptoms and manifestations characteristic of the particular tissue or organ involved.

Morrow says: "Venereal diseases possess certain peculiarities in their origin and mode of communication which distinguish them from all other infectious diseases." Prostitution, promiscuous sexual intercourse, is the principal source, and prostitutes the most active disseminators of venereal infection, but the idea that these diseases, more especially syphilis, have their exclusive origin in licentious indulgence is erroneous, and productive of much harm. Buckley of New York says: "Syphilis is certainly not a venereal disease in all cases. In fact, it is no longer so classified by the Committee on Prophylaxis of Venereal Diseases of the Washington State Medical Association. Infection of a new-born babe by the wet nurse, or of the latter by an innocent infant with inherited syphilis, account for numerous cases of pox. Personal effects of syphilitic patients such, for example, as eating and drinking utensils, pipes and cigars, manicure and shaving instruments, or toilet articles, may and frequently have been active carriers of the specific virus. Still other means of innocently acquiring and transmitting the disease are: Promiscuous kissing; surgical and dental work, when either party to the contract may unconsciously communicate the dreaded disease to the other, and the ritual of circumcision as practised by the Jewish rabbi.

With gonorrhea the mode of contagion is nearly always genital, 70 per cent. being traceable to prostitution. Patients very frequently testify to having contracted their case from some public comfort station. Statistics show and physicians believe that but comparatively few cases are ever thus conveyed. With public towels and utensils used in common, the chief danger as regards gonorrhea arises from the liability of transmitting the poison to the delicate membrane of the eyes, there setting up a violent inflammation, with blindness as the sad but inevitable result unless speedily and properly treated. In such cases unclean fingers are frequently the indirect exciting agents responsible for conveying the discharge. Unconsciously rubbing the eyes supplies the missing link in the vicious circle.

Syphilis and gonorrhea alike claim many victims wholly unsuspicious of the fact that they are the active transmitters of the contagion. Syphilis is contagious for years and may be transmitted to the offspring even when the person affected is apparently free from it. Because an active discharge has stopped does not necessarily signify that a given case of gonorrhea has vanished; it may perchance be latent, biding its time, later to infect husband or wife or mutual friend. The undisputed fact that many are affected with syphilis or gonorrhea without any suspicion of it and without any one's being able to detect any signs of disease on them, accounts in a large measure for the dire results following in the wake of prostitution, legal or clandestine.

No consideration of venereal diseases and their prevention can be complete without a brief allusion to this ancient evil upon which they are founded, together with some of its underlying causes, and the various methods for its restraint or suppression. Prostitution is the result of the operation of no single cause, but of the interaction of two or more. An apparently inherited weakness toward lewdness may be discerned in some cases. Valentine believes that "females given to a lewd life are not made prostitutes by anything except an innate tendency thereto." He also says: "The fact seems to be that degeneration is the cause of prostitution." Ludwig Weiss well expresses his conception of the hereditary factor in the following quotation: "There is present on one side an atavistic, dormant propensity toward polygamy in man, a developmental defect as it were, mitigated by religion, education, and self-control; and on the other an almost extinct inclination for polyandry in the female, present in an almost negligible quantity." A fruitful source of prostitution and the known origin of numerous cases of venereal diseases is the almost universal ignorance of the young people of both sexes regarding (1) the sexual instinct and the need for controlling it, (2) the possibilities of conception, (3) the danger and mode of contracting "private" diseases.

Some eminent authorities fail to seriously consider either the hereditary or the anthropologic factors in cases coming under their observation, and variously attribute the existence of prostitution and venereal infection to alcoholism, man's lust, lack of proper moral training, and existing social or economic conditions. The socio-economic factors, if not the greatest element in the causation of prostitution, surely would seem to rank as preeminent incentives. Immigration, child labor, women in industrial life, poor and inadequate housing facilities, together with other less apparent factors in our social fabric, "converge to bring forth the prostitute."

Coeval with the existence of prostitution have been the variously inspired efforts for its suppression, regulation, or limitation within prescribed boundaries. History would seem to teach us that we can never hope to eradicate this evil and with this teaching the leading students of the subject are in accord. The French method of dealing with the social evil is one of compulsory official supervision, the so-called system of reglementation. It requires registration and periodical examination of all licensed prostitutes. Opponents of this system claim that it places a premium on secret prostitution. Naturally it does not reach the great army of clandestine prostitutes who may continue in their evil ways and disseminate venereal diseases without restraint. Perhaps the most serious defects in the system are: (1) "The chief offender, the male purveyor of venereal diseases, is allowed perfect freedom, being completely ignored in the reckoning." (2) The system of medical examinations is a farce and only serves to give a false sense of security to the participants, since at its best it offers no absolute security. Valentine is very outspoken on this phase of the question, and says: "Systematic examinations of their genitals, even twice daily, would be of no avail, for between two such examinations a prostitute can easily infect twenty men." The same author also claims that an examination for gonorrhea alone can not conscientiously be done in less than ten days. Dr. Davis, Health Officer of Cincinnati, claims as the result of weekly examinations of all known prostitutes under his jurisdiction "a very material decrease in the number of cases of venereal diseases in the city." Morrow states that "the system has proved defective as a sanitary scheme and is condemned by its practical results." With but few exceptions in the United States public opinion, at least in its present state, will not tolerate this official method of checking a manifest danger to the public health.

Believing that all methods aiming at suppression of the evil are not only futile but unjust and inhuman, and noting the very obvious defects in the system of compulsory official supervision, some of our leading authorities on the subject are advocating a geographical restriction of disorderly houses within certain limits. Spencer of San Francisco gives it as his opinion that such resorts are "self-segregating in most communities." Opponents of this method of regulating vice claim that such a plan breeds familiarity with the evil in the minds of our youth.

"Venereal infection stands as the prototype of evils made possible by the ignorance of the public." In this particular class of diseases various motives aid in its concealment: prejudice, public sentiment, and the code of professional ethics are known factors working against public enlightenment. Ignorance being one of the most potent causes for the existence of syphilis and gonorrhea, our constant aim and ambition must be to impart a knowledge of the truth and correct the many fallacies now permeating the minds of our youth. Education alone can greatly modify this potent cause for evil.

Any comprehensive study of venereal prophylaxis demands a rational consideration of the sexual instinct. This natural impulse in mankind means the perpetuation of the species, and constitutes "the most important function, from a biological standpoint, of which any man or woman is capable." (Denslow Lewis.) Its impelling force demands recognition, and requires satisfaction, and when rightly directed becomes a pure and noble function; when misapplied or perverted very serious results

frequently follow. The necessity of accurate knowledge pertaining to this dominant force, and all incidents in its manifestation, has not until very recent times been fully appreciated. The value of publicity regarding sexual matters no longer being denied, a consistent exposition of the various sexual truths should prove our most effective weapon in fighting the social evil and checking the spread of venereal diseases. Morrow ranks the education of the public as the most valuable of all measures for the prevention of communicable diseases and says: "Its importance is emphasized in the case of diseases the communication of which lies entirely within the control of the individual."

There seems to be a unanimity of opinion among the leading genito-urinary men as to the necessity of education in any efficient scheme of venereal prophylaxis. Just what knowledge shall be diffused; the proper channels for its distribution; to whom it shall be given; who shall be the instructors and at what age it shall be imparted are points upon which the various authorities differ. I can do no better than present for your consideration this evening certain facts and opinions, culled from various reliable sources, bearing upon these points.

As to the instruction of children in sexual matters, Cumston (of Boston) and Carrier (of Detroit) claim that parents should be the teachers. Where such are wanting, or inhibited through ignorance or false modesty, school instructors or the family physician have been suggested by some. Marcy (of Boston) believes it "the duty of the experienced to teach the inexperienced and of those who are wise to teach the ignorant." Herdman (of Ann Arbor) and Whiteside (of Portland, Ore.) believe that it is in work such as the instruction of girls along these lines that the high-minded woman physician will find a sphere of activity and great service peculiarly her own. I fully agree with Keyes of New York that "an example of an ideal man for such work among young men is the Y. M. C. A. (and the college) physical director. He is one-half teacher and one-half medical man and is vitally interested in the problem of sexual and venereal diseases." I have taken it for granted that the physician, be he regimental surgeon, general practitioner, or member of hospital or dispensary staff, should do his utmost to instruct those under his care as to the origin, spread, and dangers of venereal diseases. "He can teach purity from the standpoint of health." (Carrier.) All should be taught: children, youth, and adults; male and female; those in perfect health as well as all bearers of venereal contagion. But the information imparted should be adapted to the pupil's age and needs. While prostitutes might well be instructed as to the symptoms of syphilis, such knowledge would hardly be needed by an innocent youth of twelve or thirteen years. Opinions differ as to the instruction of girls. Valentine (of New York) feels that "sexual physiology and hygiene need not be formally taught girls, save in the exceptional instances in which the genetic impulse is prematurely developed." Marcy would teach each and every boy and girl, beginning at puberty, the laws of reproduction and the dangers of their violation. Dorsey (of Chicago) believes that young people should learn "how the sexual instinct manifests itself and how it may be controlled."

The consensus of medical opinion, briefly stated, is that our youth and maidens should receive full instruction regarding sexual physiology and hygiene and the results of frivolous indiscretions. Nor are there several authorities greatly at variance as to the age at which to introduce these subjects to the young mind. Valentine places that age at the time "when mental and sexual puberty make him capable of beneficially utilizing the knowledge." H. S. Pomeroy (of Boston) puts it, "as early as the dawn of puberty"; Bailey (of Harvard), "before the young man goes to college." Cumston tersely states the time as "in youth" and so clearly expresses his reasons for this period of life that I will quote him verbatim: "To be salutary as a safeguard, therefore, this hygienic education should be given in youth, for it is during this period that the foundations of what may be termed the sexual character are formed, which, in great measure, determine the future sexual life of the individual."

Personally I believe in a progressive sexual education with the parents as the first and most natural instructors. As the child imbibes his knowledge of the care of the eyes, the ears, and other parts of the body, so let him absorb information concerning the sexual organs. Teach him the proper care of them. Differences in sex, life reproduction, and the perpetuation of the species may be taught and illustrated by lessons in botany, gradually working up to the biological world as the child advances in years. Just as soon as his own sexual organs become objects of curiosity, we might the better instruct him as regards the physiology of the sexual apparatus and the dangers following its abuse. Knowledge of sexual matters the children and youth of our land are bound to acquire, and if we fail to enlighten them by a consistent exposition of the truths pertaining to their sexual lives, other and perverted sources will probably furnish the knowledge in an impure and distorted form. Without doubt, the several municipal and state boards of health would constitute suitable channels for the distribution to the general public of scientific facts pertaining to these diseases. Circulars of information and instruction issued from such sources would carry the weight of authority. Physicians might act as the direct distributors of such pamphlets, using their discretion as to the proper disposal of the same. The Committee on Prophylaxis of Venereal Diseases of the Washington State Medical Association are pursuing this plan and the pamphlets already issued are admirable in purpose and contain a fund of information and instruction for the unenlightened.

Another rational and practical method of educating a certain element of the public is through the employment of somewhat similar circulars distributed at our dispensaries to every sufferer from a venereal affection. To me they would seem to fulfil one of the chief functions of such an institution, namely, the education of its patients concerning their own needs and their relations to other people. Dr. Dillen Cabot (of New York) was instrumental in introducing this system of instruction into the outdoor department of the Presbyterian Hospital and his instruction slips to sufferers from syphilis and gonorrhea furnish valuable information in a concise and lucid form. The State Board of Health of Indiana, through the various dispensaries within its jurisdiction, is distributing similar leaflets, so-called "bulletins," on tuberculosis, syphilis, and gonorrhea. Their secretary, Dr. J. N. Hurty, says: "We hope by this means to do some good." I believe his hopes will be abundantly realized.

In any efficient scheme of education pertaining to the grave and difficult problem of venereal prophylaxis, numerous fallicies and superstitions of the public mind must first be met and exposed. Otherwise we labor in vain. Teach the public: (1) That

continence is compatible with health, or, as Peterkin well states it, "continence, if mental and physical, is not incompatible with health." (2) The stoppage of the visible discharge is positively no proof of the cure of gonorrhea. (3) The comparison of gonorrhea with a severe "cold in the head" is a grave error and far from the truth. (4) Syphilis is curable. (5) Venereal diseases may be innocently acquired; that they have their exclusive origin in licentious indulgence is a misconception and an untruth.

Education, as one of the social forces, will greatly help in checking the spread of these diseases. Knowledge alone, however, will not always suffice, since medical students and unmarried physicians are by no means strangers to venereal infections. Education, reinforced by that fear which comes of knowledge, frequently acts as a deterrent of sexual perversions. Whiteside claims that the fear of contracting such diseases prevents only the cowardly. In answer to this McDonnell (of New Haven) would say, "but fear, a most powerful, if ignoble sentiment, probably prevents more crime and misery than natural disinclination and moral obligations combined."

Teachers of criminology also tell us that fear seems to be stronger than anything else in the prevention of crime. It was Eschylus who said so many, many years ago, "It is good that fear should sit as a guardian of the soul, forcing it into wisdom."

Until within quite recent years venereal diseases have had practically no official existence, and but scant recognition from our health boards. For years known and classified as communicable diseases, they alone among the several bodily infections, have been unmolested and unreported. One of the strongest recommendations recently proposed by a sub-committee composed of Drs. Morrow, Weiss, and Fowler of New York was the one declaring that "the regulation and prophylaxis of venereal diseases should be wholly in the hands of the Board of Health." Physicians should be required by law to report the nature and source of all cases of venereal disease, solely for statistical purposes, suppressing the names of the individuals: this recommendation to include hospitals and dispensaries.

In conclusion, let us bear in mind the fact that infinite tact, patience, and perseverance will be necessary to check the spread of this public peril. The desired end can only be approximated, and "health will continue to be a matter of right living in the individual."

THE NEED OF EARLIER DIAGNOSIS.*

By J. N. HALL, M.D.,

DENVER, COL.

PROFESSOR OF MEDICINE, DENVER, AND GROSS COLLEGE OF MEDICINE.

In the ordinary case of acute disease, the diagnosis is likely to be made early by the average physician with a good deal of accuracy. In many cases of chronic disease the exactitude of the diagnosis is of comparatively little consequence. A few months lost in the determination of arteriosclerosis, interstitial nephritis, locomotor ataxia, or a hundred other chronic diseases would not very materially alter the patient's comfort or the final outcome of the disease. But I wish to speak of another class of affections, in which the life, or at least the happiness and efficiency of the individual, depends upon early diagnosis and consequent proper treatment.

In pulmonary tuberculosis there are several weeks in the beginning in which every moment is precious. The patient with a few rales in one apex and a degree of temperature at night, with slight, hacking cough and a loss of ten pounds in weight, is curable in the great majority of cases. After dullness, expectoration, night sweats, and tubercle bacilli appear, half the chances are gone, and after extensive dullness is evident, nearly all of them. There is no difficulty in finding the signs and symptoms mentioned, yet most of the cases of tuberculosis we see were not properly diagnosed in this stage, and have suffered accordingly. The failure of early diagnosis and prompt treatment here, as in the other examples I shall give, is not because the physician does not suspect what the trouble is, but that he fears to act until he has absolute evidence to justify his action. He fails to have the courage of his convictions while there is still time to save the patient.

Another good illustration of my subject may be found in a certain type of diphtheria. A concrete example will serve us best. I saw, with two other physicians, a baby ill for thirty-six hours, with gradually increasing hoarseness and laryngeal obstruction. Nothing was found in the throat or nares by the laryngologist called, and diphtheria would not have been even suggested had it not been for the known fact that acute obstruction at the larynx is so commonly of this nature. A good dose of antitoxin was given at once, and a culture from deep in the throat was sent to the Health Office. When the report came back positive the next day the baby was already convalescent from the laryngeal diphtheria. This diagnosis was not at first grounded on any sound physical basis, nor was it positive, but it was timely, and it saved the baby's life.

I have seen dozens of cases of pleurisy with effusion or empyema which went on week after week under a diagnosis of unresolved pneumonia, or with no definite diagnosis of any kind, in which the physician had perhaps refrained from using the exploring needle because he feared there was no fluid there. The man who finds fluid every time he uses the needle utterly misses the greatest usefulness of this means of diagnosis. It should be used when we *fear* that fluid is present, rather than when we become reasonably sure of it. Neither should one be discouraged by one or two unsuccessful punctures. I have recently seen a case of empyema with a very small cavity, which had partially emptied through a bronchus, in which careful examination by six or seven physicians failed to locate the trouble. On the twelfth puncture, under an anesthetic, it was found, and resection of rib with drainage resulted in prompt recovery. In abscess of the liver we find the same difficulties.

I saw a physician a few years ago who had been so anemic for a year or two as to be unable to continue his practice. He was examined by an excellent clinician, and told that the microscopic examination of the blood did not make the diagnosis of pernicious anemia certain, although it rather looked like it. He was advised to eat nutritious food and be in the open air much of the time! Thus he went on for a year longer. By acting upon the principle that a well-grounded suspicion of pernicious anemia justified rest in bed and vigorous arsenical treatment, I was enabled to restore him to his place in the profession, although he died a year or two later in a relapse. Inability to make an exact classical diagnosis is no ground for withholding a vigorous treatment according to the best light we can obtain.

*Read by invitation before the Utah State Medical Association, Salt Lake City, May 7, 1907.

Perhaps the best class of cases to study to illustrate the points we wish to make, is that great one in which the chief symptom is abdominal pain, generally recurrent, and extending over months or years. Thousands of these sufferers, with a diagnosis of gastralgia, chronic indigestion, chronic gastritis, and other "blanket" forms of diagnosis, meaning little but covering up much, are taking bismuth, Fowler's solution, phosphate of soda, various kinds of "pain-killer," and, sad to say, morphine and other anodynes. Yet most of them might be permanently cured in a fortnight if only the physician could have the courage to make a probable diagnosis on what signs and symptoms there are, and act upon it, instead of waiting for years, perhaps, for jaundice, hematemesis, perforation of one of the viscera or some other sign equally conclusive. Then something is often done, although frequently too late for the poor patient.

Thus the diagnosis of gallstones ought to be made in most cases long before jaundice appears, but in a multitude of cases it is not. We ought all to take to heart the lesson that jaundice is a late, accidental, and, on the whole, rather infrequent accompaniment of gallstone disease. While its presence is often a great comfort to the medical mind, its absence should be regarded as of little more import than the absence of morning vomiting in an otherwise well-marked case of pregnancy.

We may make precisely the same statements concerning hematamesis in gastric ulcer. Many, perhaps most, patients having persistent sour stomach and occasional vomiting, have ulcer of the stomach, yet we are all prone to give an alkaline mixture and wait for further evidence. A month's rest in bed with rectal feeding and the usual treatment for ulcer will cure most of these patients. If it does not, the surgeon should be consulted.

Patients with chronic appendicitis continually appear who have had obscure pains in the abdomen for years, without an accurate diagnosis. Yet a skillful examination will detect a trifle of rigidity in the right lower quadrant, and tenderness, perhaps very moderate, over the appendix. Inquiry as to any acute attacks is perhaps fruitless, although history of attacks of "colic" may be easily obtained. A little further inquiry perhaps shows that the patient stayed abed with a sore abdomen for a day after the so-called colic. I have seen many patients with no further indications than those who had lost 25 to 60 pounds, and who immediately recovered after removal of a kinked appendix showing the thickening of previous inflammations. I have just seen one such patient operated upon, in whom the first acute attack occurred after he had engaged his room at the hospital and set the day for operation, and it perforated just before the time he had selected. Had he taken the trip he had intended into the mountains first, the result might well have been fatal.

Many cases of cancer of the pylorus might be saved did we not delay exploration month after month, while seeking positive evidence of cancer, or the contrary, by repeated test meals, blood examinations, et cetera. If the patient is not operated upon until a tumor can be felt, cure is generally only a remote possibility. We ought rather to be guided by the broad general rule that a patient of middle age with progressive loss of weight, continuous stomach symptoms, and lack of HCl presumably has cancer or chronic gastritis. If the means used for treatment of the latter condition do not soon bring relief, exploration is in order, that we may not sacrifice the patient's sole chance for recovery to our craze for an exact diagnosis.

One could easily quote scores of similar cases, but they are unnecessary for our purpose. My object is to bring before you the idea that, while exact diagnosis is extremely desirable, we can pay too high a price for it in sacrificing the best interests of our patient while we seek it. When we see smoke coming from a window we call the fire department first and investigate the exact source afterwards. When we see suggestive symptoms in our patients we should be prepared to act upon them as though they were more decisive, and not let our patient die while waiting for an ideal diagnosis. We should cultivate the courage which we all need to advise exploration early in obscure abdominal cases, even in the absence of decisive symptoms if the patient is not doing well. Especially must we be careful not to disregard suggestive symptoms because of the absence of others often or even usually associated.

I speak the more strongly because I have yet to see, after a reasonably wide experience, a case in which the abdomen was opened for such signs and symptoms as we have noted, without finding a justification for it in the shape of some condition capable of relief surgically. Many times it has not been just what was expected, but that is the experience of all who see these cases, I am sure. If one or two symptoms point clearly toward some abdominal lesion, and are persistent, we are safe in advising exploration if they are not relieved by medical means, and are sufficiently troublesome to the patient.

Neither should we be too easily shaken in our opinion because of the addition to the clinical picture of extraneous signs and symptoms, nor because of the absence of features common to most such cases. Few clinical pictures are absolutely complete. One perfectly clear and positive sign should outweigh a ton of negative evidence. I shall, in closing, quote briefly two cases illustrative of these points.

I have to-day seen, with Dr. C. B. Lyman, a woman of forty years operated upon by him for acute appendicitis six weeks ago. Through the incision the gall-bladder was examined in the routine way and found negative. We all realize that such an examination is of great value if positive, but of much less worth if negative. After leaving the hospital she had a severe colicky pain in the epigastrium, requiring a hypodermic injection of morphine. Tenderness and rigidity were present over the gall-bladder. A history of a similar attack a year ago was obtained. Jaundice had not been present. We agreed upon a fairly positive diagnosis of gallstones. Upon opening the gall-bladder sixty-six small calculi were removed. There were no adhesions. These stones had evidently been in some portion of the gall-bladder inaccessible to the examining finger, or were too small to be palpable.

The other case I have recently seen with Dr. Leonard Freeman. He had operated upon a middle-aged woman of marked hysterical tendencies for chronic appendicitis eleven months before, with relief for some six months. Then pain in the upper abdomen recurred. He had, through the original incision, examined the gall-bladder, and found it negative, and there were no signs of peptic ulcer. A test meal was given and gastric digestion was found normal. For a few months tonics were prescribed under an unwilling diagnosis of gastralgia. After temporary improvement she returned to Denver and reported pain as severe as ever in paroxysms, requiring the use of morphine hypodermatically. She was well nourished and without jaundice. She had very slight tenderness, and per-

haps a trace of rigidity below the gall-bladder region. She had well-marked hysterical hemianesthesia on the left side, very sharp knee jerks, and much decrease in corneal and pharyngeal reflexes, and on the evening preceding the time set for an exploratory operation a paroxysm of hysterical screaming, sobbing, and general unruliness. With some anxiety as to the possible hysterical nature of all of her symptoms, the abdomen was opened. Thirty-nine gallstones were found in the gall-bladder, two being lodged in the cystic duct. The gall-bladder was adherent to the colon, in all except its distal third, so that the stones, which were lodged in a much sacculated ampulla could be detected only with difficulty until the adhesions were separated, thus accounting for their having escaped the examining finger during the previous operation. I must express my admiration for the excellent judgment displayed by both these surgeons in remaining open to conviction by new evidence in spite of the previous negative findings.

These cases perhaps enforce the ideas I wish to present better than any others I could adduce. We must be more and more prepared to assume the responsibility for a tentative diagnosis and for subsequent treatment, without so much loss of time in waiting for a classical diagnosis. With such abdominal cases as we have indicated, and in many others affecting the chest and other regions of the body, we should explore early rather than await the advent of pathognomonic symptoms, with the unavoidable advance in the underlying pathological process.

TWO UNUSUAL CAUSES OF RECTAL HEMORRHAGE.

By CHARLES B KELSEY, M.D.,

NEW YORK.

THE first case was as follows: A man, a giant in stature, six feet four and heavy in proportion, was treated by a well-advertised quack in New York for "piles and ulcers," by the "injection method." Two weeks after his last injection, while riding in his carriage, he was seized with a sudden and increasing desire for a movement, stopped at a hotel, and emptied the bowel of a large quantity of blood. Shortly afterwards this had to be repeated, and, feeling weak and frightened, he started for his home up the river. Twice on the train the same thing occurred, and he was finally carried into his house unconscious and supposed to be dead. The fainting saved his life, as so often happens, and a couple of weeks later he was at my office for treatment.

Examination revealed a complete fistula on one side of the rectum, where an injection had burrowed its way out, and a deep, ragged ulcer in another part, the size of a half dollar, where a slough had occurred as the result of another injection, and from which the bleeding had come.

I have now, as a result of personal observation, and experience, placed before the profession a series of cases showing the bad results of this one method of treatment. Enumerated briefly, these results are: Painful swelling and edema of the subcutaneous tissue at the anus lasting for weeks, even when the injection has been well above the sphincters; marginal abscesses causing fistulæ; deep pelvic phlegmon with lymphangitis, and resulting incurable fistula; severe ulceration at the point of injection; dangerous and nearly fatal bleeding from such ulceration, and finally death from septic poisoning.

This is a pretty severe arraignment of any surgical method. In fact, I have personally encountered more accidents from this one method of treating piles than from all other recognized surgical methods combined. It is a fascinating scheme till tried, and I think I notice a tendency on the part of some of the younger proctologists to use it and advocate it. One or two of the smaller abscesses cooled my own ardor years ago, and for the benefit of those of less experience, who are honestly seeking to do good work, I would put this case on record.

The second case was this: I was telephoned to come to my office in the middle of the afternoon for a patient who was bleeding, and found a badly frightened man, whose clothing confirmed his story, being pretty thoroughly saturated. His statement was that his piles had been tied off under local anesthesia with water some hours before and that he had been bleeding ever since.

Examination with a speculum showed two wounds at the margin of the anus, a spouting artery just within the grasp of the sphincter, and a knotted ligature lying loose in the rectum. The vessel was sealed by a touch with a galvanocautery. Incidentally there was revealed a very sizable group of internal hemorrhoids which had *not* been operated upon.

This method is another to which I have never given my allegiance, though I do a great deal of office work under local anesthesia. But, as I have said before, I have never been able to see any originality, brilliancy, or surgical good sense in using drams of water where drops of an anesthetic would do, and I can see many objections. The case reported shows only one of them, and the sponsor for this particular procedure himself calls attention to the unusual number of hemorrhages in his own practice resulting from it, and is inclined to think they may have been due to some unknown action of the adrenalin he was using, and which he has therefore ceased to use. Is it necessary to look for some unknown physiological action of a drug for explanation? How would the very well-known surgical fact that ligatures do not hold well in edematous tissues suffice?

To my own mind the danger of bleeding is inherent in the method which consists in first rendering the parts to which ligatures are to be applied artificially edematous to the point of actual devitalization and calling this local anesthesia.

44 EAST TWENTY-NINTH STREET.

Tuberculosis of the Kidney.—McMillet reviews a series of cases from which he draws various conclusions. He thinks that the source of the kidney infection should be searched for, although most often none can be found. From the nature of tuberculous lesions in other organs, occasional cure of tuberculous foci in the kidney by hygienic measures might be expected. With this in view, operation might properly be delayed in the acute infection, the case being kept under observation. Surgical intervention is indicated by progressive loss of kidney function and signs of bladder involvement. A certain percentage of the acute cases have a low resistance, and the kidney manifestations are but the local signs of disease which, in a few weeks, may be demonstrated in other organs. The gradual destruction of kidney tissue in one organ is as gradually accounted for by hypertrophy of the other. The removal of the diseased kidney is indicated before it becomes a drag on the function of the sound organ. The manifestations in the individual case must offer the main indications as to the proper time for operation.—*The Journal of the Minnesota State Medical Association and The Northwestern Lancet.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, August 3, 1907.

KERNIG'S SIGN IN CEREBROSPINAL MENINGITIS.

In hospital practice lumbar puncture has of late become the readiest means of diagnosing cerebrospinal meningitis. In private practice, however, the procedure often meets with insuperable objections from the relatives of the patient, while at other times the necessary conditions for the aseptic tapping of the spinal canal may be lacking. The older signs of the disease, therefore, have not been given up, and of these, Kernig's sign, first described in 1884, has, perhaps, received the most attention. The opinions of its value are varied indeed; some claim to have found it in many other diseases, others miss it oftener than find it, while still others describe its presence in healthy individuals. Thus Wennagel, writing in the *Deutsches Archiv für klinische Medizin*, 1906, claims to have observed the sign in some 12 per cent. of patients suffering from diseases other than cerebrospinal meningitis. On the other hand, Netter, who has done most to popularize the sign, considers that it is of great value in the diagnosis of cerebrospinal meningitis complicating other diseases, and, in a paper presented at the Thirteenth International Medical Congress in Paris in 1900 (Comptes rendus du XIII. Congrès international de médecine, Paris, 1900, Vol. IV., p. 157) reports over three hundred cases of typhoid fever in which he has succeeded in finding this complication by making use of Kernig's sign.

In a recent series of papers (*Russkii Vratch*, Nos. 18, 19, 20, and 21, 1907) Kernig himself reviews the evidence, and brings abundant statistics gathered by him since 1884, in reference to the sign named after him. Perhaps his most imporant claim is that many authors have not used the correct technique in eliciting his sign, and hence have obtained such varied results. Wennagel, for instance, tested his patients, correctly enough, in the sitting posture, with the thighs at right angles to the trunk, but considered the sign to be present if the patient fell over backward when an attempt was made to extend his leg upon the thigh. Kernig, on the contrary, only begins to look for the presence of his sign at this stage; he has the trunk of the patient supported, so that his thighs and trunk are constantly at right angles, and considers that his sign is elicited if the extension of the leg upon the thigh proves to be impossible in this position.

Many authors have observed the disappearance of the sign with the onset of paralysis, or after a lumbar puncture, as well as its untrustworthiness in the case of little children. Kernig throws interesting light upon these facts in discussing the causation of this phenomenon. He refers to Roglet's theory (Contribution à l'étude du signe de Kernig dans les meningites, Paris, 1900) that the increased intracranial pressure and the irritation of the roots of the spinal nerves by the presence of an exudate produce a hypertonic condition in the muscles of the legs; of these, the hamstring muscles are physiologically too short to allow complete extension of the leg upon the thigh, when the latter is at an acute angle with the trunk. Becoming still shorter because of the excessive tone of their fibers, they now do not permit such extension of the leg, even when the trunk and the thigh are at right angles to each other. If this theory is correct, then the loss of Kernig's sign must of necessity follow the onset of paralysis with the loss of muscular tone accompanying this condition. Spinal puncture, too, diminishes the pressure upon the roots of the spinal nerves, and may thus reduce their excessive irritability and the heightened tone of the muscles innervated by them. The frequent absence of the sign in children may be explained by the greater relative extensibility of their muscles in the presence of the superior force of the examiner's hand.

Kernig's experience with typhoid fever patients differs from that of Netter, for in a series of one hundred and sixty-eight cases of this disease he found his sign but twice. He explains this apparent disagreement by the presence of an epidemic of cerebrospinal meningitis in Paris at the time of Netter's observations. It is interesting to note that of the two typhoid patients in whom Kernig had positive results, one came to autopsy, showing extensive chronic leptomeningitis, while the other was found to be suffering from tuberculous disease of the spine in the lumbar region. In many cases of middle ear and mastoid disease Kernig has seen his sign, and indeed considers its appearance as the last warning that the meninges are irritated by hyperemia or by extension of the infection, and that the case therefore requires immediate surgical interference.

Kernig's valuable papers ought to reawaken interest in the sign discussed, and lead to a careful reconsideration of its value. In all future clinical study of it, however, Kernig's explanation of the technique used by him in eliciting the sign ought to be carefully observed.

THE NATURE OF ADDISON'S DISEASE.

KOHN'S discovery of the chromaffine system in the adrenal bodies and sympathetic ganglia, as well as the clinical observations in this connection made by Wiesel, Chvostek, and others, have done much to aid in an understanding of the irregularities often observed in the symptom complex known as Addison's disease. Kohn gave the name of chromaffine cells to certain cells having the property of elective staining by means of the salts of chromic acid. These occur in the medullary substance of the adrenal bodies, in the so-called paraganglia of the same organs, in various portions of the sympathetic system, and in the carotid gland. The workers in this field believe that the active principle of the adrenals is contained in the chromaffine cells.

The corresponding cells of the sympathetic system are supposed to have the same properties as those of the adrenals, and when the latter are destroyed hyperplasia of the chromaffine bodies of the paraganglia and the sympathetic is supposed to take place and compensate for the deficiency. Wiesel has expressed the view that Addison's disease is a primary affection of the chromaffine system and may begin in the suprarenals or in the sympathetic system. The disease may therefore be present even though the cortical substance of the adrenal is intact, and, on the other hand, it may be absent even if there is pronounced disease of the adrenals, provided that the other chromaffine cells exert their compensatory function.

Granting such a well-designed compensatory mechanism in the chromaffine system, it is rather singular that so few instances have been reported of cure of Addison's disease, and in this connection an interesting suggestion is made by Grawitz (*Deutsche medizinische Wochenschift*, July 4, 1907). He is of the opinion that Addison's disease does not depend on a single etiological factor, and that it may be the result of causes other than primary degeneration of the adrenal body or the chromaffine substances. As an example, he mentions the so-called vagabond's disease, in which discoloration of the skin and buccal mucous membrane occurs in poorly nourished and usually alcoholic individuals. In this condition he believes that the chronic malnutrition is the underlying cause of the cutaneous discoloration, and similarly cases of severe asthenia with bronzing of the skin may depend on interferences of nutrition resulting from affections of the intestinal tract. Belonging to the same category are cases of severe cachexia usually classed with the group of pernicious anemias, although the blood changes frequently are not altogether characteristic of this disease. All of these affections have in common the existence of severe gastrointestinal disturbances, and Grawitz is of the opinion that such cachexias may be produced through chronic intoxication originating in the alimentary tract. In corroboration of this theory, he reports two cases of Addison's disease, which he regards as having been permanently cured by gastric lavage and carefully regulated diet. A further possibility is that the intestinal intoxication may serve to impede the regeneration of chromaffine substances in cases in which the adrenals are already damaged, and that in this way an explanation may be found for the infrequency of cure in Addison's disease, notwithstanding the natural tendency to compensation exhibited by the chromaffine system.

THE PHYSICAL CONDITION OF WEST POINT GRADUATES.

There is a widespread, if not universal, impression among both physicians and laymen that the physical and nervous condition of West Point cadets is about as near perfection as human ingenuity can make it. They are under absolute control; their food, exercise, clothing, studies, and almost every detail of life, are matters of minute regulation; the prevention of disease is given most careful consideration, and the least symptom of illness is brought under the control of skilled physicians. Excepting minor mild outbreaks of measles or mumps, or some such imported infection, the history of the Academy is said to be devoid of any serious sickness, much less of any epidemic.

Nevertheless, it is well to take occasional stock of our fixed opinions, and find out if they are really based on facts. All professions have had occasion to reverse themselves. It was only yesterday that we sent away our rich tuberculosis patients every winter, but now we shamefacedly confess that they improve most in our winters, and least, or not at all, in the summers, and that we were formerly sending these invalids away from the conditions which cured them. West Point is a national institution of vast importance, and everything involving its welfare is deserving of the widest publicity. If there are any errors of management they must be known and corrected, and the responsible authorities will no doubt give suggestions the consideration they deserve.

The correspondent, whose letter is published in another column, has touched upon several matters which have received more or less attention in recent years. It is well to pause and think over his suggestion that the training at West Point is too strenuous for immature bodies. The lean, fine-drawn athlete does not receive the indorsement from the medical profession he once did, for there is too large a proportion of life failures among that class. The untrained often succeed because they are unstrained. The suggestion as to insufficient sleep is vital and deserves consideration, for surely such boys need more than they get. It is difficult to judge of the success of West Point graduates, because so few ever have an opportunity for distinction, but it is strange, nevertheless, that we hear of such a small percentage who do distinguish themselves. Non-graduates filled the public eye during and since the Spanish war, and some of them have the reputation of being great men, in spite of much criticism as to their lack of military training in youth. Was this fact really in their favor?

The methods of West Point are essentially those of laymen. Until comparatively recently the medical officers were never consulted as to such matters. If there really is a condition of strain, either physical or nervous, as a result of an overstrenuous life of these growing and immature boys, it ought to be known and remedied. The matter deserves investigation, for mere denial will not suffice—particularly denials from laymen who do not understand what is meant by nervous exhaustion or overstrain, which may exist even if there is fine muscular development.

The Treatment of Cerebrospinal Meningitis.

The old saying that desperate diseases require desperate remedies seems to be exemplified by a suggestion in regard to the treatment of epidemic cerebrospinal meningitis made by Radmann in the *Münchener medizinische Wochenschrift*, July 2, 1907. He points out that the therapeutic problem to be solved is to find some means of aiding the body in its reaction against the meningococcus. The attempt to accomplish this by means of artificially produced antibodies has not been very successful, however; at least none of the serums hitherto tried appears to have given very promising results

as yet. Radmann undertakes to increase the powers of resistance in a somewhat different way. Starting with the observation that meningitis does not follow the subcutaneous inoculation with meningococci in animals, and that the organisms must be introduced into the subdural space in order to produce the disease, he assumes that the subcutaneous tissue is unfavorable for the development of the meningococcus, and that in disposing of local depots of bacteria in this situation the excess of reaction would prove advantageous to the body as a whole. He accordingly in two cases injected some of the patient's own cerebrospinal fluid subcutaneously in the arm. No local reaction was caused, and recovery followed in both instances. It need hardly be said that before resorting to such an expedient the diagnosis of a pure meningococcus meningitis would have to be assured, for even in a mixed infection the results at the site of injection would probably be disastrous, while in cases of a different origin the procedure would be wholly out of the question.

Diagnosis of the Source of Indicanuria.

Indican is derived from indol, a decomposition product of albuminous substances, and is found only in very small quantities in healthy urine. There are three possibilities as to its origin: (1) in the intestine by the decomposition of albumin under the influence of bacteria; (2) in pus foci where large quantities of albuminous substances are undergoing rapid decomposition, as in empyema; (3) in the body cell in cases of disturbed metabolism such as cachexia, hunger, etc. We can readily see that any method which would enable us to ascertain from which one of these three it originated would be of material aid in making a differential diagnosis in complicated cases. With this in view, B. J. Slowtzow carried on an exhaustive series of experiments as a result of which he came to the following conclusions (*Russkii Vratch*, No. 7, 1907): When the indican is of intestinal origin, the amount is moderate, reaching its maximum in from four to five hours after meals, it is diminished by a milk diet and by the ingestion of bismuth, while alkaline waters increase it. When of pyogenic origin, the amount is large, reaching its maximum at night and bearing no relation to meals or to the ingestion of milk, bismuth, or alkaline waters. When it finds its origin in the body cell the amount is uniform throughout the day, and bears no relation to the ingestion of bismuth, while milk and alkaline waters diminish it.

The Use of Alcohol by Medical Men.

The alcohol discussion in England has received a fresh impetus through a feature of the recent annual dinner of the Medical-Psychological Association. Sir James Crichton-Browne obtained from the manager of the dining-room a record of the amount of alcohol collectively and individually consumed by the diners, and in the course of a toast to science he said that there were at the table eighty-four members of the Association. Of them 6 per cent. had declined alcohol, although all the rest, 94 per cent., had partaken of alcohol in some form, and a large majority in several different forms. A fortnight before he had dined at Sir Andrew Noble's table with eighteen of the leading men of science of the day, from the venerable Lord Kelvin down, and not one of them declined alcohol. In view of such facts, he said, it would be a farce or obsession or gross hyperbole to speak of alcohol as a deadly poison. Those who declared alcohol to be a deadly poison should also state that we constantly carry about in our bodies more deadly poisons or toxins, but these human poisons were harmless, and might be beneficial so long as they were kept in their right places, and our great aim should be to keep alcohol also in its right place.

Is There Typhoid Fever at Jamestown?

The little outbreak of typhoid among the West Point cadets, as a result of their visit to the Jamestown Exposition, to which a correspondent has referred in an arraignment of West Point methods, is a matter of national concern, for it is evidence of serious mismanagement somewhere, and public opinion will not tolerate excuses if there has been wrongdoing. The public has been given to understand that there is no typhoid fever in or about the Exposition, but there have been persistent rumors that it is present there, nevertheless; and it is even said that Camp John Smith, where the regular troops are quartered, is not entirely free from the disease, despite the excellent sanitary regulations in force there, to which we referred last week. If typhoid fever is present at Jamestown the public should be so informed, and intending visitors should be warned so that they may take the necessary precautions. We presume the War Department will publish all the facts in due time, but anything of this nature should be made known at once, and not after the damage has been done.

Treatment of Constipation by Abstinence from Meat.

Treatment of constipation by purgatives alone is not regarded with favor by the majority of practitioners, and even a diet which leaves a large amount of residue to act as a stimulant to the intestines does not give good results. Kohnstamm (*Zeitschrift für Physikalische und Diätetische Therapie*, June 1, 1907) depends chiefly on butter and milk, with the absolute exclusion of meat, to overcome chronic constipation. He begins treatment with a purgative and an enema, after which he waits four or five days for a natural stool. If this does not occur another enema is given, but under no circumstances another purgative. The patient is then put on a diet consisting of oatmeal, milk, bread and butter, honey, eggs, soups, vegetables, fruits, and cocoa. He reports several instances in which excellent results have been obtained, even in cases of ten years' standing. Other cases failed because the patient became lax and discontinued butter, or added meat to the dietary.

Potassium Permanganate in the Treatment of Snakebites.

Much has been written on the use of potassium permanganate as a remedy for poisonous snakebites, and while some claim it is of no value whatever, others laud its beneficial action. This difference of action seems to depend largely upon the mode of administration of the drug. When given hypodermatically in any part of the body, irrespective of the location of the bite, it is useless. One can hardly expect to affect an organic poison, which has already or is about to spread through the entire system, by injecting a remedy such as potassium permanganate subcutaneously into any part of the body. The small amount injected can have only a

local oxidizing effect, for the drug acts merely as a chemical antidote, as ferric hydrate does to arsenic, and magnesia to the inorganic acids. Diesing (*Archiv für Schiffs- und Tropen-Hygiene*, Vol. XI., No. 11, 1907) has used permanganate successfully, however, in the following manner: As soon as possible a tourniquet is placed above the bite, and potassium permanganate (about one to two cubic centimeters of a one per cent. solution is sufficient) is then injected subcutaneously around the wound, entirely encircling it; the poison, which has not as yet been absorbed, is thus oxidized and made harmless. Any general symptoms which may already have set in are treated in the usual way with whiskey, etc. In certain regions where venomous snakes abound many of the inhabitants habitually carry vials containing a solution of potassium permanganate and use it in the way just described.

News of the Week.

Tugboat Whistles.—Capt. Ira Harris, Supervising Inspector of the Local Steamboat Inspection Service, has announced a decision in regard to the unnecessary use of steamboat whistles. The decision declares that the use of tugboats of "private code" whistles is unlawful, and is forbidden by Section 12 of Rule 10 of the steamboat regulations. The use of the siren in waters where the ordinary whistle will serve is also condemned. This ruling is approved by George Uhler, Supervising Inspector General at Washington, the head of the service. The decision was made in the matter of appeal of a tugboat captain who was fined last April for unnecessary whistling.

Copper Converted into Lithium?—It is reported by cable from England that Sir William Ramsey has declared that by making use of radium emanations it is possible to "degrade" copper to lithium. This is being heralded as the realization of the alchemist's dream of the transmutation of metals. It will be recalled, however, that discussion of the transmutation of elements at the meeting of the British Association last year arising from the apparent production of helium from radium led to a vigorous controversy in which Lord Kelvin and other eminent men repudiated the transmutation theory, which was strongly supported by Sir Oliver Lodge and others.

South Dakota Board of Medical Examiners.—At the annual election the following were chosen members of this Board: A. A. Cotton, Vermillion, *President;* H. S. Graves, Hurley, *Vice-President;* H. E. McNutt, Aberdeen, *Secretary;* J. M. Walsh, Ft. Pierre; F. S. Howe, Deadwood; F. W. Freyberg, Mitchell; L. G. Hill, Watertown.

Suicides Among School Children in Germany.—Suicides among school children and young persons are stated to be greatly on the increase in Germany. Prof. Eulenburg is reported as saying that during the last twelve years he has traced 1,152 cases of children's suicides, more than half of whom were driven to it by failure in their school examinations or overwork at school.

Tuberculosis in the War Department.—Owing to the discovery of five cases of tuberculosis among the employees of the insular bureau of the War Department, its rooms in the State, War and Navy buildings have been sealed and fumigated.

Doctors as Cooks.—A Berlin physician, Dr. Wilhelm Sternberg, is endeavoring to bring about the introduction of a course in cookery into the medical curriculum. He considers that doctors are in the habit of prescribing a diet for their patients with regard only to its chemical ingredients, forgetting the importance of an appetizing method of preparation.

Stony Wold Sanatorium.—This institution has received a bequest of $1,000 from the estate of the late Mrs. Anna Meyer of New York.

Death of a Centenarian.—Mrs. Catherine Moore of Rahway, N. J., died on July 27. She is stated to have been born at Tuckahoe, Md., on July 24, 1795, and was therefore a few days more than one hundred and twelve years of age.

Dr. J. Playfair McMurrich, professor of anatomy in the University of Michigan, has resigned in order to accept a similar position in the University of Toronto.

The Chicago School of Sanitary Instruction was recently incorporated by officials of the Chicago City Health Department, with a view to extending knowledge of public health matters, and training men to be Civil Service Sanitary inspectors. Those interested are: Dr. W. A. Evans, Health Commissioner; Dr. F. W. Reilly, Assistant Health Commissioner; Dr. J. H. Biehn; Dr. C. W. Behm, Chief of the Disinfection Service; Dr. Heman Spalding, Chief Medical Inspector; Dr. M. O. Heckard, and Charles B. Ball, Chief Sanitary Inspector. No charge will be made for instruction, and the students will be given practical work with the inspectors employed by the city.

The Woman's Medical Society of Illinois was recently incorporated by Dr. Marion K. Bowles of Joliet and Drs. Sara C. Buckley and Bertha Van Hoosen, Chicago. It is stated that the purpose of this organization is to bring into closer touch the women physicians of Illinois, with a view to securing cooperation and the promotion of all objects of interest to women in medicine; likewise for increasing interest in the membershp of the Illinos State Medical Society.

Free Distribution of Antitoxin.—The Secretary of the Illinois State Board of Health recently announced that the law providing for the free distribution of diphtheria antitoxin by the Board went into effect July 1, but that on account of the delay in the details of purchase and manufacture the supplies will not be ready for distribution before October 1. In the meantime physicians can secure antitoxin from any of the agents of the Board without cost to the poor, on obtaining an order from the supervisor or overseer, as required under the Act of 1905.

Yorkville Hospital.—The Board of Directors of the Yorkville Hospital, formerly known as the Metropolitan Hospital and Dispensary, in order to meet the increased demands upon the institution, has decided to add to the present medical board additional visiting physicians and surgeons in surgery, gynecology, internal medicine, orthopedics, and diseases of the eye, ear, nose, and throat. The directors announce that the selection of the physicians will be made solely on professional merit regardless of social, political, or financial influences.

Bequests to Charity.—By the will of Mrs. S. A. R. Moses, filed last week in the Surrogate's office, $5,000 each is given to the Brooklyn Home for Consumptives and the Cottage Hospital of Laconia, N. H.

Leprosy in Boston.—The Massachusetts State Board of Health is said to have confirmed the diagnosis of leprosy made in the Massachusetts General Hospital in the case of a woman who has recently been

employed as a domestic servant in a number of well-known Boston families. The patient, who has been under treatment for a year as suffering from some obscure skin affection, has been sent to the State leper colony at Penikese Island, off the coast, near New Bedford.

Proprietary Remedies in Germany.—At its last year's meeting the Freie Vereinigung der Deutschen medizinische Fachpresse, an association having as its members the editors of most of the prominent German medical journals, decided to prepare a list which should comprise the names of medical writers who are known to accept remuneration for laudatory articles written about proprietary remedies, the members of the association pledging themselves not to print contributions from these authors nor to abstract them. After careful investigation, in which it is stated that strangely enough many chemical firms were of great assistance, such a list has been prepared and distributed. The result will no doubt be beneficial to both medical journalism and the medical public.

Funds for Consumptives.—The Charity Organization Society appeals for contributions to aid its committee on tuberculosis in its work. The committee is caring for sixty or more consumptives on board the old Staten Island ferryboat *Southfield*, the use of which has been donated by the city. Three thousand dollars, it is estimated, will enable the committee to pay for this whole undertaking and to continue it on its present scale until November 1. Contributions may be sent to the society at 105 East Twenty-second street, New York City.

Railway Accidents.—An official of the Archive Bureau of the Prussian Railway Administration has prepared a comparative table of statistics of those killed and injured by railways in various countries. He finds that, both absolutely and relatively, the railroads in the United States are the most deadly. The United States has more mileage than all Europe, but, even taking that into consideration, the United States holds preeminence in proportional figures. Out of every 1,000 railway employees the ratio of the number injured each year is as follows: United States, 43.5; Switzerland, 25.3; England, 11.8; Belgium, 11; Germany, 2.4. Out of every ten thousand employees the relative figures of killed are: United States, 26.1; England, 12.3; Switzerland, 8.2; Russia, 7.8; British India, 6.7; Belgium, 4.1. In a single year—the fiscal year of 1902-3—76,500 persons were injured in the United States, of whom 60,000 were employees, and 9,800 were killed, of whom 3,600 were employees. In the matter of travelers injured, France holds the lowest record in the world. The United States shows proportionately forty times as many as France; Russia twenty-two times as many; Italy twenty times as many; England eight times as many, and Germany twice as many.

An Infection from Tainted Money.—A paymaster of the U. S. Army in the Philippines has had to have an arm amputated as the result of an infection alleged to have been received from the money handled in paying the troops.

"Archives of Pediatrics."—Beginning with the July number of this monthly, Dr. R. S. Haynes has been associated in an editorial capacity with Dr. L. Emmett Holt, the editor of this interesting journal.

An Oriental Opium Cure.—A report has been received from Consul Lester Maynard of Sandakan in regard to an opium cure said to be used with good results in the Straits Settlements, and which has lately been introduced into British North Borneo. A decoction is made by boiling the leaves and mixing the result with opium. After smoking, a dose of two tablespoonfuls of the drug is to be taken, and this is said to lessen the desire for further indulgence. The drug is known to the Chinese as Tong Hing Chu. Mr. L. Wray, curator of the Taiping Museum at Perak, has identified the plant as "*Combretum sundaicum*." It is abundant on the plains around Kuala Lumpur, in Selangor. The properties of the Combretaceæ, the natural order to which it belongs, are very little known. Some are used in malarial fevers, two are known to possess vermifuge properties, and one is used for poisoning bats. A few preliminary tests applied in the research laboratory of the Pharmaceutical Society of Great Britain to the small quantity of the leaves available indicate only the presence of an astringent principle and a coloring matter, but do not afford a definite proof of the presence of any alkaloid or glucoside, although the leaves appear to contain some substance as yet unknown to chemists.

Rutland County (Vt.) Medical Association.—At the meeting of this society held at Lake Bomoseen on July 16 officers were elected as follows: *President*, Dr. A. H. Bellrose of Rutland; *Vice-President*, Dr. J. F. Estabrook of Brandon; *Secretary*, Dr. C. F. Ball of Rutland; *Treasurer*, Dr. H. R. Ryan of Rutland.

Upper Peninsula (Mich.) Medical Association.—At the meeting of this organization held in Menominee on July 19 the following officers were elected: *President*, Dr. B. T. Phillips of Menominee; *Vice-Presidents*, Dr. C. L. Gerard of Escanaba and Dr. W. T. S. Gregg of Calumet; *Secretary*, Dr. H. J. Hornbogen of Marquette. Marquette was selected as the next meeting place.

Maritime Medical Association.—The sixteenth annual meeting of this organization was held in St. John, N. B., July 18. Officers were elected as follows: *President*, Dr. M. Chisholm of Halifax, N. S.; *Vice-Presidents*, Dr. G. E. Dewitt of Wolfville, N. S., Dr. Anglin of Fairville, N. B., and Dr. Jardine of Summerside, P. E. I.; *Secretary*, Dr. Melvin of St. John, N. B.; *Treasurer*, Dr. Farrish of Yarmouth.

New Brunswick (Can.) Medical Association.—The twenty-seventh annual meeting of this association was held in St. John, N. B., on July 17. Officers were elected as follows: *President*, Dr. J. M. Deacon of Milltown; *Vice-Presidents*, Dr. J. R. McIntosh of St. John and Dr. A. J. Ferguson of Dalhousie; *Secretary*, Dr. R. G. Day of St. John; *Corresponding Secretary*, Dr. C. T. Purdy of Moncton; *Treasurer*, Dr. G. G. Melvin of St. John. It was decided to hold the next annual meeting in St. Stephen.

Obituary Notes.—Dr. Lee McElroy of Elizabeth, N. J., died on July 26 in the Alexian Hospital of that city after an illness of several months. He was born at Bardolph, Ill., thirty years ago, and received his medical education in the North Western University at Evanston, Ill. He had been a resident of Elizabeth for two years.

Dr. George T. Ballard of Hampden, Mass., died on July 18, at the age of sixty-six years. He was born in Holland, Mass., and had practised in Hampden for forty-five years. He was graduated from the Berkshire Medical College in Pittsfield in 1862. He had repeatedly served as selectman and school commissioner.

Dr. Oliver LaCrone of Kalamazoo, Mich., died in Chicago on July 19, at the age of forty-eight years. He had practised in Kalamazoo for fifteen years, and at one time was candidate for the office

of Mayor. He was a graduate of the Michigan State University.

Dr. FORREST L. ESTILL, son of Dr. J. T. Estill of Colorado Springs, died in that city on July 15, at the age of twenty-seven years. He was graduated from the Washington School of Medicine in St. Louis in 1903.

Dr. SAMUEL BISHOP of Muscatine, Ia., died on July 20, at the age of eighty-one years. Dr. Bishop was born in Ohio, and practised for many years at Moline, Ill.

Dr. A. J. RADIKE of Burlington, Vt., died of abscess of the liver on July 17, at the age of fifty-four years. He was born in Germany, but came to this country while a young man, and was a graduate of St. Joseph's College at St. Joseph, Mo. He had practised in Burlington for about twenty years.

Dr. WILLIAM F. BOOR of Newcastle, Ind., died on July 17, at the age of eighty-eight years. He was born in Perry County, Ohio, and was graduated from the Jefferson Medical College at Philadelphia in 1853. After practising for a time in Middletown, Ind., he removed to Ohio and later to Newcastle, where he had since resided. He was a charter member of the Henry County Medical Society, was surgeon of the Fourth Indiana Cavalry during the Civil War, and in 1870 was appointed U. S. Pension Examiner.

Dr. ROBERT O. CRAIG of Janesville, Minn., died on July 15, at the age of seventy-four years. He had been a resident of Janesville for thirty-five years, and had served as State Senator.

Correspondence.

THE BAD PHYSICAL CONDITION OF WEST POINT CADETS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The newspapers have stated that a large number of West Point cadets were made sick by their stay at the Jamestown Exposition and some two or three contracted typhoid fever. No such reports have been published as to the large number of cadet schools which went to the Exposition and lived in similar unsanitary conditions, and it seems, therefore, that West Pointers are unable to resist infections or adverse conditions which are harmless to others.

This is amazing, in view of the frequent publication of accounts of the physical perfection of the West Pointers; how they were selected with such care and trained so as to reach a condition which cannot be improved—an opinion from which there does not seem to be a dissenting official voice. Indeed, there appears to be a resentment of any criticism of the management of the health of these immature boys. Nevertheless, I once had a chance to see the cadets and was painfully impressed by their bad condition, which, on retrospection, fully accounts to me for their lowered vitality and resistance. This condition has evidently existed so long that the authorities, who have never seen anything else, have come to regard it as normal, though in reality it is a dangerous abnormality. Some of the cadets were well nourished, a few actually fat, but the great majority had thin, drawn features and very slender figures, suggesting emaciation. They seemed to have been "worked down" or "trained" to a condition which the progressive element in the profession now recognizes as one of dangerous exhaustion, with little surplus for emergencies.

It is said that they are not permitted enough sleep, being forbidden to retire before a certain hour and routed out before they obtain eight or eight and a half hours in bed, whereas schoolboys of that age must have nine or even ten hours' sleep. The life of snappy activity uses up all energy and the cadet reaches the end of the school year more or less exhausted and spends a great deal of his vacation in sleep. These facts explain what has always seemed a medical paradox. The cadets are the pick of a large number of applicants, larger indeed than the student body of a large university with its hundreds of physical weaklings, and yet in athletic games requiring the best physique they do not shine. In the mental sphere, few are ever heard from, while the small colleges, which formerly paid no attention to physical training, have graduated a large number of noted men. Perhaps some of this may be due to the fact that West Point is a technical school, and these boys, being trained for war, do not have chances for distinction in peace. Yet the age of seventeen is too young to begin a strenuous technical education, and the last board of visitors has advised a change.

Nevertheless, there is an outcry in the profession against too much physical training in our colleges, and it seems to be well grounded, for it is apparently illustrated by the thin, drawn countenances of these cadets and the mental exhaustion which is reached at the end of their overstrenuous school year.

It may seem unwise to criticise, not having any remedy to offer, except the suggestion that immature boys should be compelled to sleep from nine to ten hours if their nervous organization is to be strengthened and not exhausted. Doubtless every official at West Point is wholly unaware that anything is wrong and will vigorously deny the need of any change. But that is the rule, for outside criticisms are always needed to effect reforms. We rarely realize the need of changing what has become familiar, and prior suggestions to remedy the course of instruction have been strongly opposed. In physical and nervous matters lay opinions are not worth much, as our college athletic abuses show.

It is said that the average West Point graduate needs a year or two to recuperate enough to take that keen delight in study which is so essential for success in any profession. If this is really so, it, too, is fully explained by the thin, exhausted appearance of those graduates, and it should be remediable without injuring that West Point discipline which is the pride of all Americans. It does seem that a change is needed, but I am not ready to make further suggestions. I have merely desired to call attention to what was seen. It does seem that we would have far better results from this splendid material if it were not so strained and exhausted in the training. M. D.

NEW YORK, July 31, 1907.

DIAGNOSIS OF RENAL CALCULUS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In a recent issue of your esteemed paper, July 6, page 23, you make mention of and comment on a new sign of renal calculus brought forward in an article which appeared in the *Münchener medizinische Wochenschrift*, June 4, 1907. Permit me to call your attention to a paper read by me before the New York County Medical Association June 21, 1897, and published in the *New York Medical Journal*, Vol. 66, page 349, 1897, entitled, "The Genital Phenomena of Renal Calculi." In that paper the "new" symptom to which you favorably refer is elaborately emphasized. R. ABRAHAMS, M.D.

NEW YORK.

OUR LONDON LETTER.

(From Our Special Correspondent.)

TROPICAL MEDICINE, INAUGURAL ADDRESS OF THE NEW SOCIETY—PROFESSOR OSLER ON MEDICAL WOMEN—KING EDWARDS' HOSPITAL FUND—ROYAL COLLEGE OF SURGEONS—OBITUARY—SIR W. H. BROADBENT, M.D., F.R.S., ETC.

LONDON, July 27, 1907.

THE Society of Tropical Medicine and Hygiene is now duly established among us, the first meeting having been held on the 28th ult. A lantern demonstration by Dr. C. W. Daniels proved attractive, important points being illustrated and the value of preventive measures enforced.

The President, Sir Patrick Manson, in his address said the great object of the society was to bring together those interested in tropical medicine, with a view of advancing the subject and benefiting the members. To secure these objects the society was placed on the broadest basis. Though domiciled in London, it was open to all, wherever they might be, who could forward directly or indirectly the progress of the subject. At one time special schools for teaching it were looked on somewhat askance, but that feeling had passed and if any one so regarded the formation of the society doubtless it would soon be approved. Comparing the state of the subject now and in the early nineties, Sir Patrick said that in Davidson's work on "Warm Climates," 1893, the carefully written article on malaria contained no word on the mosquito. Laveran's discovery had been before the world twelve years, but they had not gone beyond the conviction that air was the medium of infection and a lingering belief in the Hippocratic idea that enlargement of the spleen was due to drinking marshy water. In the recent edition of Allbutt's "System"

a large part of the section on tropical medicine was occupied with the part played by the mosquito, and everyone recognizes how this has changed our views of malaria and given an impetus to the study of the rôle of insects in the spread of diseases. We cannot claim so great an advance as to cholera, leprosy, and beriberi, but as regards sleeping sickness everything has been revolutionized. We now know that it is the terminal phase of a trypanosoma infection, hitherto unrecognized in human pathology, that the immediate cause of the sleeping is infiltration of the lymphatic spaces of the brain with certain small mononuclear cells, that the disease is conveyed by the tsetse fly, and that to some extent it is amenable to treatment by arsenic, mercury, and certain dyes. The tropical fluxes were not mentioned and unfortunately their etiology and treatment is in an unsatisfactory state. The *Amœba* and the *Bacillus dysenteriæ* do not cover the field and the knowledge of their existence has not helped treatment. In tropical helminthology numerous additions might be claimed. Chief among them was Looss's discovery that the larvæ of *Ankylostomiasis* gained access to the body through the skin. The term relapsing fever covered a number of infections, spread probably by as many ticks or other blood-suckers. A number of the diseases of lower animals had also great importance in regard to tropical pathology. The study of blood-suckers had become so vast that its teaching had had to be relegated to special men. In Davidson's day they had only one culex to consider; nowadays nearly 600 species of mosquitos, with the ticks, flies, etc., were objects for study. The president said there were many other discoveries in the last thirteen or fourteen years, but he had said enough to show how great had been the progress. He added that not only had their horizon been thus widened, but many additional workers were in the field. This extraordinary increase was no doubt accounted for by the establishment of tropical schools both at home and abroad, as well as by the encouragement of the British Government. The calling of an international conference on sleeping sickness by H. M. Government showed they were entering on a new era. All over the British tropical possessions laboratories were being established for the investigation of these diseases and the assistance of practitioners. These laboratories had begun to bear fruit and the president had no doubt that ten years hence they would have important discoveries and an enormous accumulation of data as a result of that enlightened policy.

The rôle of the society was to bring them abreast of what was being done by that army of workers, so that they might be in the best position to do full justice to tropical cases and to lend a hand in advancing the knowledge of tropical diseases and hygiene.

Professor Osler presented the prizes at the Women's School and in his speech told the students that many women were specially adapted to work at the highest problems of scientific medicine. He instanced bacteriology, histology, and even pathology as peculiarly suitable. Asylum work was another important line. He would like to see in every asylum one or two women physicians. General practice was hard enough for men and he was sorry for women who had to face it. As to special practice among women and children, to which many would like to see them restricted, Dr. Osler remarked that women did not believe much in men, but they believed much less in women. Amid the laughter and cheers thus excited he added, "that was one of the serious problems in connection with the progress of women." His advice to them was, therefore, so to conduct their lives that others would have trust in them. Another branch of special practice suited for them was in connection with schools. If a paternal government established a system of school inspection, he thought women could do the work more satisfactorily than men. One more field of work he mentioned was that of India and the Mission field. In this there seems to be room and to spare for medical women.

The bill for incorporating the Kings' Hospital Fund has undergone considerable alterations in its progress through Parliament. The changes made, it is understood, are in accordance with the King's desire that whatever safeguards were thought desirable should be provided. On the termination of the presidency by the Prince of Wales it is arranged that the Lord Chancellor, the Prime Minister, and the Governor of the Bank of England at that time shall be requested to recommend a member of the Royal Family (being a son, grandson, or brother of the sovereign). Further, the president will be controlled by the council as to the appointments, expenditure, and distribution of the funds. To test the power of the president will be, by his [illegible] limited to the collection of money. Thus [illegible] will have all the advantages of the close connection with the Royal Family which created and has thus [illegible]. Considering that about £100,000 a year [illegible] for the Hospital by this fund, it is only natural that it should be continued on similar lines. It is also agreed that the fund shall be annually audited, the auditor being appointed by the president of the local Government Board for the time being. In various quarters there have been proposals for representation of hospital managers on the council, but it would obviously not be in accordance with ordinary prudence to make such persons judges of their own proceedings by giving them a voice in the amount of money to be awarded to their respective hospitals.

On the question of larger representation of the profession on the council there is a difference of opinion, some holding that one or two eminent leaders suffice, others maintaining that they should be reinforced by a considerable contingent.

The annual election of Councillors at the Royal College of Surgeons—an event which always excites some interest, took place on the 4th inst. More fellows voted than on any previous occasion—800 out of the total 1,166. Mr. Chartens Symonds of Guy's headed the poll. Messrs. Moullin and Eve of the London Hospital and Mr. Bruce Clarke of St. Bartholomew's were also elected.

Yesterday the Council met and the new members were received. Mr. Henry Morris was reelected president. Messrs. Watson Cheyne and Rickman Godlee were elected vice-presidents for the ensuing year, and the professors and lecturers for the year were appointed.

Sir William Broadbent died on Wednesday, the 10th inst., and is to be buried to-morrow. Born in January, 1835, he took his M.B., Lond. in 1858, M.D. 1860, M.R.C.P. 1861. He had taken the scholarship in physiology, an exhibition in anatomy, and gold medals in midwifery and chemistry. He was an alumnus of Owens' College, Manchester, where also he distinguished himself. He was one of those to whom opportunity comes early and was well equipped for it. He took an appointment at the Western Dispensary, but it was not long before he was elected assistant physician to St. Mary's Hospital, where he continued for his life work, passing through all the posts to the consultant staff, and taking an active part in the school in which he was for so many years the lecturer on medicine and clinical medicine. He was also for a number of years physician to the Fever Hospital. At the College of Physicians he was elected Fellow in 1869, Examiner from 1876 to 1884, Councillor 1885-1886, Croonian Lecturer 1887, Censor 1888-1889-1895, and Lumleian Lecturer in 1891.

By this time he was in the enjoyment of an extensive practice as a consultant. He attended the Prince of Wales (then Duke of York) during his attack of typhoid fever, 1891, and was appointed Physician Extraordinary to Queen Victoria the next year, and in 1898 became Physician in Ordinary on the death of Sir R. Quain. He had received his baronetcy in 1893. He had on several occasions attended the late Queen and was one of her physicians in her last illness. His court appointment was continued by the King on his accession, and in His Majesty's illness at the time of the coronation Sir William was in close attendance.

Sir W. Broadbent contributed freely to the journals and societies. He has served as president to several of these, including the Medical of London, at which he delivered the Lettsomian lectures on "Syphilitic Affections of the Nervous System." Neurology was one of his favorite subjects. Another, not at all second to it, was the circulation, as his book on "Heart Disease" and that on "The Pulse" sufficiently attest.

As a speaker or lecturer Sir W. Broadbent could not be described as attractive. But he was a successful teacher, as he had a way of impressing essential points on his students. One of them said to me: "He seemed rather dry at first, but I soon saw how deep and accurate his knowledge was and somehow he made you remember the most essential things."

Last October Sir William Broadbent had an attack of influenza, with pleuropneumonia, followed by empyema. He was progressing well when a second attack of influenza prostrated him and he did not convalesce. On the 6th severe rigors set in, with other signs of endocarditis, and he succumbed on Wednesday.

The Food of French Workmen.—Professor Landouzy, in a recent address, quoted statistics showing that among the working classes of Paris the men spend on an average 1 franc and 14 centimes a day for solid nourishment, and 1 franc and 24 centimes a day for drink. The women are almost always underfed, the cost of their food averaging only from 1 franc to 1 franc and 10 centimes a day, as compared with 2 francs and 38 centimes for the men, and in consequence they age early. He asserted that nearly all laborers eat too much meat, the proportion in expense being 60 per cent., while in nutritive value it is only 8 per cent.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.

FRAMBESIA IN THE SAN LAZARO HOSPITAL—HEALTH HINTS TO NEWCOMERS—NEW PHILIPPINE MEDICAL SCHOOL—SPRUE—PERSONAL NOTES.

MANILA, P. I., June 15, 1907.

THE theory that frambesia, or yaws, is found only among persons who live in dark, damp, unsanitary places would appear to be open to considerable question, in view of the outbreak which has occurred recently among the inmates of the San Lazaro Leper Hospital. The hospital contains an average of 220 patients. On March 1, one, who had been an inmate for over a year, was noticed to be afflicted with yaws, and before seven days had passed there were three additional cases, and in the succeeding fourteen days there were two more, the last case being reported May 12, making a total of seven cases. The persons afflicted were all under sixteen years of age, and none of them had been out of the institution for many months previous. Specimens taken from the lesions and examined microscopically showed a spirochete similar to that described by Castellani. The San Lazaro Leper Hospital is not an ideal building by any means, yet the quarters of the lepers are well lighted and ventilated, the plumbing is very good, and the subsistence furnished is excellent, so that the disease could scarcely be attributed to unsanitary surroundings.

The Bureau of Health has issued a set of brief hygienic rules, which are particularly intended for new arrivals in the Philippines from temperate climates. Experience has demonstrated that the most serious diseases of the tropics are easily avoided if a few reasonable precautions are taken. The rules are as follows:

"It is easier to maintain good health in the tropics than in the United States, but in order to do so you should observe the following simple rules:

"1. Be vaccinated to-day. The Bureau of Health will do it free of charge.

"2. *Never* drink any water unless it has been either boiled or distilled, or eat any raw vegetables. If you observe this rule carefully you will probably never contract dysentery, typhoid fever, cholera, or any other disease that originates in the intestines. Disregard of this rule is responsible for the return to the United States of over 50 per cent. of the invalids who leave these islands.

"3. Fruit is wholesome, and may generally be eaten raw with impunity, provided it is of a kind that grows upon trees, well above the ground.

"4. Avoid patent medicines. Do not put drugs of which you know nothing into bodies of which you may know less.

"5. Alcoholic stimulants are not necessary, the advice of 'old residents' to the contrary notwithstanding.

"6. Generally, disease-carrying mosquitos fly only at night; therefore, always sleep under a good mosquito net.

"7. Otherwise observe the same hygienic rules that are applicable to temperate climates, including physical exercise."

The new Philippine Medical School, which is being started under the auspices of the Government, and which is eventually to be part of a Government university, is now an accomplished fact. A Government building, located on the Malecon drive, has been set aside for this purpose, and the necessary alterations to adapt it for a medical college have been made. The city morgue will be removed to the building, so that any pathological material which may become available through such a source may be taken advantage of. Nice, light, airy lecture-rooms have been provided, and excellent quarters are available for histological, pathological, bacteriological, and chemical laboratories. The first year class commenced work on June 10 last. The course is to be five years. It is quite probable that in the near future, if sufficient applicants present themselves, advanced classes will also be started. The curriculum is most complete, and compares favorably with that of first-class colleges in the United States. The entrance and graduation requirements are in accordance with the rules of the American Association of Medical Colleges, which should ensure a high standard of education. The Santo Tomas Medical School, which has been in existence for a great number of years in the Philippines, has been much stimulated by this competition, and extensive alterations have been made, courses have been changed, new teachers have been engaged, so that medical education in the Philippines has received a decided impetus during the past few months.

While cases of sprue have been reported heretofore from the Philippines, yet the disease is not commonly met with. Recently, however, another case was admitted to the Civil Hospital, of which there could be very little doubt about the diagnosis. All the characteristic symptoms were present, namely, extreme soreness of the mouth, symptoms of indigestion with feeling of weight, oppression and gaseous distention after eating, frequent vomiting; pale, grayish, pasty, fermenting and offensive stools; absence of ameba, alternate diarrhea and constipation. Improvement immediately followed when the patient was placed upon exclusive milk diet.

The recent order of the War Department that the tour of duty of staff officers in the Philippines should be reduced from two and a half to two years, has had the effect of relieving many medical officers from further duty in the islands. Among those who will leave on the transport which sails from here June 15, 1907, are Major F. A. Winter, Major Francis J. Ives, Major Paul Shillick, Major Alexander N. Stark, and Major Aaron H. Appel.

Dr. William J. Mallory, formerly chief of the Benguet sanitarium division of the Bureau of Health, has resigned his position and will engage in the practice of his profession in Washington, D. C.

Dr. R. P. Strong, chief of the biological division of the Bureau of Science, has been named as the official delegate of the Philippine Government to the Hygienic Congress, which will be held in Berlin during the month of August.

Progress of Medical Science.

New York Medical Journal, July 20, 1907.

Chancroid and Its Complications.—A. H. Uhle and W. H. Mackinney give a general description of chancroid. Nothing essentially new is presented. Concerning treatment they state that in the more virulent forms of chancroid the spread must be checked by cautery, curette, or nitric acid applied in general narcosis, and the wound treated with strict antisepsis. In some cases a continuous bichloride bath is required to limit the spread of infection. All operations are those arising from necessity. Excision of the chancroid cannot be recommended as a curative measure, as the healthy tissue invariably becomes infected with a greater destruction of tissue than if Nature's method had had its way. If phimosis is present lateral or dorsal solits should be made and antiseptic dressings applied; if paraphimosis exists it should either be reduced by one of the various mechanical methods or, this failing, the constricting band must be divided. In all cases, especially the virulent forms, attention must be given to the general health and hygienic surroundings of the patient.

Pelvic Tumors in Little Girls.—J. C. Kennedy reports the case of a girl of eleven years, attacked by sudden and intense abdominal pain. Examination led to abdominal section, and a typical dermoid cyst of the left ovary was found, weighing two and one-half pounds. Although no torsion of the pedicle was found on opening the abdomen, it was, in the author's opinion, undoubtedly the cause of the sudden and severe pain. He adds some statistics on the occurrence of pelvic tumors in children.

Treatment of Acute General Peritonitis.—G. Chandler lays down the following rules: (1) Use ether anesthesia always and operate quickly. (2) Always make a median incision and handle the bowel gently. If gas escapes a perforation is present. When little or no odor is present, the lesion is high up in the gastrointestinal tract, as ulcer of stomach or duodenum. If a foul odor is present, the lesion is low down and is usually the appendix. Where lymph is present in the intestines there usually is found the lesion. After finding this, repair quickly or remove diseased appendix. (3) Do not wash out the abdomen under any conditions. (4) Always drain the lowest portion of the pelvis through the lower angle of the incision. If necessary make multiple drains by puncture wounds in the flanks. (5) Elevate the head of the bed at least 18 inches and keep the patient in an absolutely upright sitting posture. Drainage by gravity ceases after the first twenty-four hours. (6) After placing the patient in bed, give continuous normal salt solution by rectum. (7) Give no food by mouth for four days, and always wash out the stomach just before the patient comes out of the anesthesia or immediately afterward. Cocainize the throat and wait at least five minutes before using tube (Ochsner's method). Feed by bowel every four hours, beginning with the second day, egg water, etc., one ounce of food with three of salt solution. (8) Morphine should be given by hypodermic injections for a stimulant, also to act as an abdominal "splint." It relieves the nervous tension and is absolutely indicated after operation. Use no other heart stimulant. (9) If pulse drops to 100° then everything looks favorable. Never pay any attention to the temperature until after the third or fourth day. If it then begins to show signs of suppuration, the pus can be reached by rectum or vagina, since by the exaggerated upright method it has gravitated to the pelvis,

and you have a pelvic abscess to deal with that has been walled off from the general peritoneal cavity. (10) On the fourth day always move the bowels by a high enema of milk one pint, and molasses one pint, mixed and warm.

The Rational Treatment of Nervous Patients.—Nothing new is presented in the paper of B. L. Bryant, but he has some strong common sense comments on the too frequent failure of the average physician to relieve the large class of functional neuroses. Often the most careful examination fails to discover any lesion or definite functional disturbance. What, then, the author asks, are we to do? Two courses have been followed in the past: one, the honest course, to frankly tell the patient that there is absolutely no physical condition that we can treat, except on general principles of rest, tonics, forced feeding, and general hygiene. The other, not so honest, to temporize by prescribing a bromide, a glycerophosphite, or some of the multitude of nerve tonics. Or perhaps we possess a static machine with large shiny wheels, and we play on their nerves, the seat of the supposed functional pain, and pockets, the shower, or the breeze, or the spark, or we bring out the new vibrator, the now necessary adjunct of the well equipped barber shop, and assure them we have just the thing, at so much per treatment. When all this has been done, and the patient still ungrateful enough to complain that she feels no better, then we advise a long vacation, hoping that in the meantime something new may turn up, which we can try on her when she comes back. At present we have held her as long as we can. The chances are that after several years of this kind of treatment from the profession our patient falls into the hands of some irregular practitioner, and perhaps recovers, a firm believer in the irregular's doctrines, and a distinct enemy to the regular profession. The trouble lies, says the author, in the fact that all the training of the regular practitioner has been along the physical or the materialistic line. He has been taught to believe that every derangement of the human organism has behind it some physical cause, either in an irritating toxine or a pathological lesion, therefore seeks for that physical cause, and applies the specific remedy. In most of the medical schools we hear nothing of applied psychology or psychic phenomena. It is along therapeutic lines suggested by the last statement that the proper treatment of functional neuroses largely lies.

Journal of the American Medical Association, July 27, 1907.

The Causation of Glaucoma.—J. A. Tenney has examined the eyes of 200 persons of all ages to see to what extent the lens encroached on the ciliary processes as age advanced. He does not find that a narrow circumlental space is necessarily accompanied with an increase of tension, as it is common for the aged; but he noticed that members of a family in which glaucoma has appeared all have a narrow circumlental space. He has not seen a narrow cornea in the cases of glaucoma observed by him; hyperopia is common, but some are emmetropes. He thinks it probable that chronic glaucoma is caused by excessive pressure of the vitreous, due to diseased blood-vessels in the uveal tract; at the same time, there is probably an alteration in the constitution of the aqueous humor that blocks the outlets. He asks why the ciliary process may not secrete albumin when age has changed the character of the blood vessels. If sympathetectomy relieves intraocular tension, it does, as he asserts, through its influence on the circulation in the choroid and ciliary process, and the same may be said of iridectomy, which does not relieve tension immediately, showing that its influence is on the intraocular circulation. Another fact pointing the same way is that in some cases of iridocyclitis with lessened tension it increases it.

Onychomycosis Trichophytina.—A. Ravogli reports two cases of this condition, one of them notable on account of the nails being primarily and solely affected. In the other case there was a preceding tinea of the scalp and the infection had been communicated to the nails by scratching. In the first case the disposition of the fungi in the nails was peculiar, splitting it up in a longitudinal way, but the cultures showed the same growth in both cases. The prognosis in such cases as that mentioned is less favorable than when the fungus is situated on the surface, as the spores cannot be reached so readily by therapeutic agents. In this special case the disease had lasted many years, and the patient would not endure the needful treatment. The other patient recovered with application of Wilkinson's ointment to the nails and scalp.

Itching.—J. D. Bulkley discusses the various forms and causes of itching and their treatment. He divides the causes into three general categories: 1. External; 2, idiopathic, and 3, constitutional. The external causes are divided by him into two groups, miscellaneous and parasitic, the first including itching from mechanical, toxic, and climatic causes. Under idiopathic causes he recognizes two groups, the neurotic, including reflex and functional, and senile causes. The constitutional are divided also into two groups, the autotoxic, acute and chronic, and the dermatopathologic causes. Each of these is illustrated by types mentioned. As specially calling for notice, may be mentioned his remarks on reflex itching induced by pruritus in other parts of the body and thus complicating itching from other causes, mechanical, parasitic, etc., and the opinion expressed by the author that dermatitis herpetiformis should be classed among the neurotic conditions as being due to some derangement of the cord or the conducting nerves. Senile pruritis, he says, stands alone, as a condition probably due to alterations in nerve structure in common with other degenerations belonging to old age. Urticaria is given as the type of autotoxic forms of itching, and most of the cases falling into the dermatopathologic group are included in a comparatively few diseases, eczema, erythema multiforme, lichen, dysidrosis, and prurigo. Most of the cases called prurigo occurring in this country, however, are, he says, chronic papular urticaria. Careful observation of the cause of pruritis is due in all cases; it is Nature's signal that something is wrong, either with the skin itself or elsewhere, and this must be sought and discovered. The reasons why pruritis is so often worst at night are given by Bulkley as the natural nerve exhaustion and consequent greater irritability at the close of the day, the greater loading of the blood at that time with the products of catabolism, the abeyance of the higher cerebral functions and external irritation, as from the cold in undressing followed by warmth in bed, etc. The treatment of itching is a large subject. The constitutional measures, when applicable, are both dietetic and medicinal, lowered general and nervous conditions predispose the skin, as well as the other organs to disease. This is especially true in neurotic cases. Analgesic internal treatment is often of service, but is often greatly misused. Opium and morphine are worse than useless and aggravate the condition; some of the coal-tar preparations have been recommended and may sometimes be of value, but they should be employed with very great caution. Among other internal remedies mentioned are cannabis indica, which is often of value when used judiciously, and chloral and bromide in combination with a little aconite added, and gelsemium, with which, however, he had once unpleasant effects. The hygienic treatment of the skin is important, and Bulkley thinks that the better class of patients are often liable to err in the direction of too much bathing. Woolen underclothing is generally best, and restraint from scratching is very important. Of medicinal local remedies, carbolic acid is preeminent and is a very valuable remedy when rightly employed. A number of other local remedies are mentioned and some formulas are given.

Opsonic Therapy in Skin Diseases.—H. R. Varney reports the results of opsonic treatment in about forty cases, twenty-seven of which were dermatological. In acne cases no other treatment was given; the patients came daily to the laboratory and their opsonic indices were determined, an average of three readings being taken. Autogenous vaccinations were then given with remarkably favorable results. Stock vaccines made from other cases of a similar type produced as good results at first, but were ineffective after the third vaccination, in no case producing a permanent cure. In five cases the guide to the revaccinations (autogenous) was the appearance of new lesions, the opsonic determination being omitted, and four of these cases have been discharged cured. Five cases of furunculosis were also successfully treated by autogenous vaccinations. In one case of coccogenous sycosis the treatment failed owing, the author thinks, to a too large beginning dose. The first dose should be a small one, as the effect is greater than with subsequent doses, and the positive phase is shortened and the succeeding negative phase, as in this case, is liable to be more marked. In another case of the same disease, rebellious to all treatment for six years, a cure followed five autogenous vaccinations. In this case the effect of alcohol and loss of sleep in lowering the opsonic index was noticeable, as was also the case in some acne patients. Excessive fatigue and menstruation also lower the index, and the physician should know his patient's physical condition before beginning treatment, and should warn him against things that are a handicap to recovery. Varney considers the method one of great value, and autogenous vaccines superior to those made of other than the patient's own invading microbe. The results can be obtained with or without opsonic determination, but will be uniformly better if thus guided.

Supervision of Tuberculosis Patients After They Leave Sanatoria.—Frederick I. Knight asserts that the proper and satisfactory control of tuberculosis in the future will involve a continued knowledge on the part of some authority not only of the individuals infected, but of their families and all surroundings. He believes that this duty should be assigned not to local boards of health, but to special local boards, who should gain the desired results with as little publicity as possible. These local boards should be composed of persons really interested in the subject, who should work cautiously and be sufficiently discreet not to create a panic in the local neighborhoods. One of the functions of such a board should be to supervise patients who, apparently cured, return home from treatment at sanatoria or elsewhere. The better class of patients will usually consult their physicians and arrange some hygienic mode of life for the immediate future; but the poorer class are sent out with some good general advice as to outdoor life, employment, etc., but with no idea how to obtain it. It is patients of this class that need to be guided. One of the most promising ways of helping to maintain the health of those restored at sanatoria is by the establishment of labor or farm colonies, where gardening, farming, raising of chickens, keeping of bees, cultivation of flowers, etc., can be carried on, with gradually increasing hours and severity of work, under medical supervision. This can be done at some of the sanatoria, where they have land enough, or at special farms devoted to the purpose, like convalescent homes. In fact, many patients, he states, could and would be better for doing some work of this kind during a part, or in some cases all of their time at the sanatoria, provided there are grounds enough to set up such regime at the institution.

The Lancet, July 13, 1907.

Bread As a Source of Uric Acid.—Attention is drawn by R. Saundby to Gautier's observation that bread may become a source of uric acid by setting free an excess of phosphoric acid, an acid that does not find any base which can neutralize it. Saundby relates the case of a boy under his hospital care for nephritis. The patient was nine years old and had swelling of the face and legs. His urine was scanty and high colored and contained blood, albumin, and epithelial and granular casts. His body was covered with numerous scabs and scratches and little raw red spots, and it seemed probable that the nephritis was caused by the absorption of some irritating substance which had been applied to the skin, although the author never was able to obtain absolute proof of this. The patient was treated at first by being put to bed in blankets and given imperial drink; his bowels were opened by scammony resin, and boric acid fomentations were applied to the sores on his legs. A week later the whole of his body was anointed daily with the following lotion: Sodium biboras, 3 drachms; oleum olivæ, 4 ounces; aq. rosarum to 8 ounces. The skin soon became perfectly healthy. The blood and casts disappeared from the urine, although there was occasionally a haze of albumin, but there was a very copious deposit of uric acid which was first noticed about a month after his admission, although he was on a diet containing only milk, bread, butter, light pudding, cocoa, and fish. The uric acid persisted in spite of various remedies. Several weeks later potatoes were substituted for bread, which was removed from his diet, and during the time he took no bread no uric acid appeared. After two days he was allowed two ounces of toast with each meal, with the result that the uric acid reappeared occasionally, so that the quantity of toast was reduced to one ounce. After three months' observation the boy seemed perfectly well and passed out from under observation, but the case goes to support the truth of Gautier's theory. He estimates that in 100 grammes of new bread there is 0.239 gramme of phosphoric acid.

The Most Frequent Hernia in Childhood and Its Significance.—A somewhat statistical presentation of the subject is made by E. M. Cornir, who notes as the most frequent and characteristic hernia of childhood the median ventral variety between the upper parts of the divaricated recti. He declares that it has never received its due consideration from the fact that surgeons have made more observations in the operating theater than in the outpatient room and have, with few exceptions, never combined these two sets of observations. This median ventral hernia is almost invariably an acquired character and is directly related to the pressure of gases produced by intestinal fermentation. Any hernia or set of hernia in any situation are more frequent when accompanied by it than when alone. Hence clinical experience shows that raised intraabdominal pressure is directly related to the frequency of inguinal hernia and, it is suggested, probably also to their initiation. It has been further suggested that the true proportion of acquired to congenital hernia is about 2 to 1. In the face of the fact that it is nearly impossible to recognize and distinguish the funicular variety of the congenital hernia sac from the acquired sac at an operation and even perhaps at a necropsy, there can be no certain knowledge of the formation of hernia in children. Therefore the author suggests that by means of the recognition of the presence and significance of the median ventral hernia, its frequency and associations, it is possible to introduce a strong probability into the question, which would seem to indicate that acquired hernias are more common in children than those due to the presence of a congenital sac. This, he says, is not a mere academic question, as the treatment to be adopted must depend largely upon its appreciation.

The Treatment of Lupus.—After a recapitulation of the methods in common use, Dr. Dreuw describes his own method, as follows: The lupus patch which is to be treated is frozen by means of ethyl chloride (or by carbonic acid gas if a deeper effect is desired) till it is snow white. Upon the frozen surface crude hydrochloric acid is rubbed in briskly and with a certain degree of force. According to Unna it is advantageous to saturate this crude hydrochloric acid with chlorine. The acid is applied in the following way. Cotton wool is wound round one end of a small wooden stick of about the size of a penholder; this is dipped in the crude hydrochloric acid and rubbed on the frozen surface, pressing slightly, till the nodules become of a grayish-white color (reaction). This grayish-white color appears first where nodules are and then in the skin surrounding the nodules. In this way a large surface can be treated at once by a succession of applications of the caustic. If the patch is very large it is best to administer chloroform. The spots are then similarly thoroughly frozen by preference with carbonic acid gas and then by the above-mentioned means the crude hydrochloric acid is energetically rubbed in. This freezing and cauterization under general anesthesia is especially suitable (1) in lupus multiplex and lupus exulcerans; (2) in lupus of the mucous membranes, the nasal cavities, the lips, and tuberculous abscesses and fistula (cauterize from six to eight times in rapid succession); and (3) where the freezing is not well borne by the patient (*e.g.* nervous and sensitive patients) or where very energetic cauterization is necessary—*e.g.* in tuberculous ulcers, lupus hypertrophicus, and verrucosus. The foregoing plan has various modifications of detail for certain bodily areas, as the nose, etc. All these points are mentioned at length by the writer. He summarizes the advantages of the method as follows: (1) It is simple, cheap, rapidly effective, and gives good cosmetic results. (2) It can be carried out at home without hospital treatment, and that is especially important for patients of limited means. (3) Complicated apparatus is not necessary, therefore the method can be applied by any practitioner. (4) The method can be applied in all forms of lupus and in all situations, with the exception perhaps of the eye. Favorable results are obtained by repeated cauterization, especially in lupus of the nasal cavity. (5) As a preliminary treatment for later Finsen treatment one gains time and gets favorable results.

British Medical Journal, July 13, 1907.

A Case of Pyonephrosis, Containing Typhoid Bacilli in Pure Culture.—The patient of F. L. Greaves was a man of thirty-six years who had had typhoid fever six years before coming under the author's observation, with a relapse. During this illness he said he had had difficult micturition, passing masses looking like liver tissue and later thick urine containing mucus. Some four months before the date of the author's initial observation of the case he had had pain and swelling in his left groin, with some vomiting and emaciation. When seen a large swelling extended from the left costal margin to about two inches from the iliac crest. It was tender, smooth, and rounded, did not descend on respiration and gave a slight thrill to the palpating fingers in front, if light percussion was made in the loin. No fluctuation was made out. Urine practically normal. By the segregation of the ureters no urine was obtainable from the left half of the bladder. Abdominal incision through the lumbar area and opening of the mass discharged pus. A large calculus was found in the left ureter. Recovery was uneventful. The only organism found in the pus, and that in pure culture, was the bacillus of typhoid. The Widal test was then tried on the blood and a positive result obtained. The calculus was nearly entirely phosphatic; although the center contained both phosphates and oxalates, the latter predominating.

Spreading Peritonitis Cured by Pelvic Drainage, Fowler's Position, and Rectal Instillation of Saline Solutions.—In reporting this case C. H. Whiteford uses the term "spreading peritonitis" in the sense of a peritonitis

in which there are no lymph barriers, but in which the inflammation has not yet invaded the entire peritoneal cavity. His patient was an anemic, unmarried woman of twenty-one years, with a history of three days' illness. Diagnosis was made of perforated, gastric, or duodenal ulcer. The method of treatment followed is indicated in the above title. Healing of the wound was completed on the twelfth day. The author highly extols the advantages of the Fowler position and, incidentally, of ether as an anesthetic in these cases, considering it most superior to chloroform. He says that surgeons who cannot operate during ether anesthesia, because of the increase in the respiratory movements, might with advantage pay a visit to the United States, where ether is used almost exclusively, and where nothing is heard of "abdominal excursions," and adds that for cases of septic peritonitis ether, especially if given by an expert, is almost ideal.

The Duty of Restoring Hearing by Operation in Chronic Aural Suppuration.—C. J. Heath relates a series of cases with comments thereon. He claims that the situation is analogous to that obtaining in appendicitis. No careful surgeon, says he, waits for abscess in abdominal appendicitis, nor, in Heath's opinion, should he wait for it in the ear. Just as removal of the appendix will eradicate the danger there, so timely elimination of the aural appendix will usually restore the ear to function and safety. The author finally came to the conclusion that if the antrum could not recover its health when there was no tympanic obstruction to its drainage, then the operation known as ossiculectomy (that is, removal of drum membrane and small bones), with the object of influencing the disease in that cavity, was futile, in spite of the sacrifice of the vibrating apparatus and consequent certainty of defective hearing. Treatment of the tympanum through the meatus, by dealing also with the effect and not with the cause of this disease, was usually found equally ineffective, and in early cases even worse. The delays such proceedings must entail were found to give time for the affection to advance beyond the point at which restoration of hearing might be brought about by operation. During operation it was also found that slight disease may exist in the mastoid antrum, yet not be identified, because of the obscuring presence of blood, and that all hemorrhage must be prevented if trustworthy observations were to be made. Finally Heath says that inasmuch as it has been shown that the mastoid antrum and not the tympanum is the chief seat of danger and disease, the old treatment must be changed. Our faith in mere lotions must abate, as they do not reach the seat of the disease. Operations now bereft of their destruction of hearing and most of their former dangers will be earlier done.

Calcium Chloride in Hemorrhage.—A. C. Lambert reports the case of a Chinese gardener of forty years who came to have two upper molars extracted. There was no remarkable hemorrhage after their removal, and the man went home, but two days later sent for the author, as the sockets were still bleeding. He must have lost a good deal of blood in the interval, judging by the amount that continued to flow during the next twenty-four hours in spite of adrenalin, plugging, and the exhibition of various styptic remedies. The patient was then removed to hospital, and given calcium chloride, grains xxx, every hour for three doses, and continued thenceforward every four hours. The sockets were firmly plugged with compound tincture of benzoin gauze. After the second dose of calcium chloride the hemorrhage ceased. The drug was continued thrice daily in 15-grain doses for two more days, when the patient returned home. He had previously suffered severe hemorrhages from a cut finger.

Berliner klinische Wochenschrift, July 8, 1907.

Experimental Observations on Renal Edema.—Bence reports the results of a series of experiments undertaken to determine the part played by the injection of uranium nitrate in the production of edema in rabbits according to the method of Richter. It has been suggested that the kidneys under the influence of the uranium salt furnishes a product having the property of inducing edema. Bence removed both kidneys from the animals and then injected uranium nitrate, finding that edema was still produced and therefore apparently was not the result of substances formed by the kidneys. The experiment was then repeated without injecting the uranium salt, the animals receiving the same amount of water as before. Both peritoneal and pleural effusions were produced, and the author concludes that marked serous effusions may be caused in rabbits merely through the extirpation of both kidneys provided that the animal survives long enough and that the loss of fluid is compensated by the administration of sufficient water. The effusions may take place without any increase in weight, and even with a loss in weight and restricted water intake, so that it appears that in the genesis of edema a factor must be active which controls the distribution of water in the tissues, blood, and tissue spaces.

Münchener medizinische Wochenschrift, July 2, 1907.

Colon Bacillus Infections.—Fehling says that the possibilities of colon bacillus infection in pregnancy are numerous and that patients and midwives should be carefully instructed in regard to the toilet of the vulva. Properly carried out it is of great value in preventing infection, but if not correctly done it may lead to the opposite result. Fehling does not agree with the observers who consider the colon pyelonephritis of pregnancy a descending infection originating from the blood, but believes that it is rather an ascending process. In one instance infection followed in the case of a primipara who was obliged to go about for some time with her clothing wet with urine, and in another it was apparently the result of improper cleansing of the vulva while in the bathtub. In these cases the primary condition was one of cystitis and the urine contained the organisms in pure culture. The colon bacilli seldom enter the blood stream, though the author describes one case of fatal colon bacillus sepsis secondary to a pubiotomy. In two cases uterine infection took place with the presence of the organisms in the liquor amnii and in the fetal circulation.

Operative Gangrene of the Rectum.—Sudeck considers the occurrence of gangrene of the rectum after extensive resections of this portion of the intestine for carcinoma and the precautions necessary to avoid this complication. He points out that the rectum receives its main blood supply through the superior hemorrhoidal artery. The middle and inferior hemorrhoidal arteries may be ligated without danger of gangrene. The gut may be drawn down only a very little way, however, without cutting the superior hemorrhoidal artery, and in order to do a high amputation it is absolutely necessary to cut this vessel, as it comes off almost in a straight line from the aorta and prevents mobilization of the intestine. If it is divided the rectum may easily be drawn down as much as is desired. The anastomoses of the intestinal arteries are peculiar in the large size of the connecting vessels, so that at any moment the function of one artery of supply may be assumed by another. By injecting the mesenteric and hemorrhoidal vessels with a lead magma and then making radiographs of the preparations the author was able to show that there is a critical point in the course of the superior hemorrhoidal artery represented by the point of union with the lowest large anastomotic branch. If ligation is performed below the critical point the rectum will not receive an adequate blood supply and gangrene is likely to ensue. If, however, the vessel is tied above the critical point the anastomotic circulation will be sufficiently active to preserve the vitality of the intestine. In order to perform the ligation at a sufficiently high point it is necessary to do the operation from above, and the author suggests that the resection of the carcinomatous rectum be performed in two sittings, at the first of which the superior hemorrhoidal artery is tied high up through a laparotomy incision and the intestine loosened from some of its attachments, while at the second the resection is performed through the perineum.

The Treatment of Gastric Vomiting with Oxalate of Cerium.—Thos. Charles Augustus Sweetnam within the last few months has been using oxalate of cerium in cases of vomiting due directly to gastric disease. He usually gives six-grain doses three times a day in adult patients, combined with ten-grain doses of carbonate of bismuth. The results have been most satisfactory. In gastric ulcer pain is relieved and vomiting ceases almost at once. The same result occurs in chronic catarrhal gastritis. Although a permanent cure cannot be expected in cancer of the stomach, the symptoms are relieved and the patient's life is prolonged. Relief in cases in which the pyloric region is largely involved can be obtained by means of surgical treatment only. The writer has also used cerium oxalate in smaller doses in cases of acute gastroenteritis occurring in children, with good results. The action of this drug is probably the same as that of the bismuth salts. It may be used in all cases in which the employment of bismuth is indicated. In many cases in which bismuth fails or produces only slight results it may effect a speedy cure, or at least afford great relief.—*The Dublin Journal of Medical Science.*

Book Reviews.

American Practice of Surgery. A Complete System of the Science and Art of Surgery, by Representative Surgeons of the United States and Canada. Editors, Joseph D. Bryant, M.D., LL.D., and Albert H. Buck, M.D., of New York City. Complete in eight volumes. Volume III. New York: William Wood & Company, 1907.

The third volume of this work appears with commendable promptness. It includes Parts XI., XII., and XIII., and treats of Poisoned Wounds, Including the Bites and Stings of Animals and Insects, Injuries and Surgical Diseases of Bones, and Diseases and Injuries of Joints. The article on poisoned wounds, from the pen of Major Charles F. Mason of the U. S. Army, includes wounds made by poisonous insects and snakes, erysipelas, anthrax, malignant edema, tetanus, and poisoned wounds inflicted by implements of warfare. The article on Rabies in this section, written by Dr. George Gibier Rambaut, contains a description of the technique of rapid diagnosis of the disease in animals by examination for the Negri bodies. The author, although asserting that the presence of these bodies is pathognomonic of rabies, does not accept them as the protozoan cause of the disease, because, among other reasons, they are not found in the saliva of rabid animals, and also because the rabic virus, whatever it may be, passes through a Berkefeld filter, which the Negri bodies cannot do.

In Part XII. the subject of Fractures is treated by Dr. Duncan Eve of Nashville; Pseudoarthrosis by Dr. P. Turner Thomas of Philadelphia; Inflammatory Affections of Bone by Dr. George A. Peters of Toronto, recently deceased; Non-inflammatory Affections of Bone by Dr. Roswell Park of Buffalo; Syphilitic Disease of the Bones by Dr. J. Shelton Horsley of Richmond, Va., and Tumors Originating in Bone by Dr. Channing C. Simmons of Boston.

Part XIII. contains the section on Diseases and Injuries of Joints. The first article in this section, "Chronic Non-tuberculous and Nontraumatic Inflammation of Joints," is by Dr. Charles F. Painter of Boston; "Tuberculous Diseases of the Bones and Joints" is written by Dr. Alexander Primrose of Toronto; the closing article is on wounds of joints, from the pen of Dr. John Chadwick Oliver of Cincinnati. A copious index completes this volume of nearly 800 pages.

The illustrations, 311 in number, are deserving of special mention for their judicious selection and the excellence of their execution. There are also eight plates, showing the Negri bodies, the architecture of the upper end of the femur, the alterations occurring in bone after its normal function has ceased, changes in the form of a long bone due to forces applied from without, tumors of bone, and radiographs illustrating tuberculous hip-joint disease, tuberculous knee-joint disease, tuberculous ankle-joint disease, and tuberculous wrist-joint disease.

Most of the subjects treated in this volume, especially the elaborate article on tuberculosis of the bones and joints, are interesting to the orthopedist as well as to the general surgeon. They are all well handled and of an encyclopedic character, leaving nothing to be desired by the seeker after knowledge, whether his object is a careful study of the subject or simply consultation. The consulter will find his task lightened and his time saved by the carefully planned index. The promise of the first volume has been well sustained by the two succeeding volumes, and it is a safe prediction, based upon these three volumes—more short of half the work—that the completed system will offer a surgical treatise unequaled in the past and difficult of approach by any that may appear in the future. The editors have done their part well in the selection of the writers and in the fitting together of their several contributions so as to make of them a harmonious whole

The Treatment of Disease: A Manual of Practica Medicine. By Reynold Webb Wilcox, M.A., M.D., LL.D., Professor of Medicine at the New York Post-Graduate Medical School and Hospital; Consulting Physician to the Nassau Hospital; Visiting Physician to St. Mark's Hospital; Fellow of the American Academy of Medicine; Member of the American Therapeutic Society and of the American Medical Association; Permanent Member of the Medical Society of the State of New York; Honorary Member of the Connecticut State Medical Society; Vice-Chairman of the Revision Committee of the United States Pharmacopœia, etc. Philadelphia: P. Blakiston's Son & Co., 1907.

This is not merely a work on therapeutics, as the title might imply, but a complete treatise on the practice of medicine, including a consideration of all the arts and sciences embraced in this subject. But the title is well chosen as a protest against the now happily waning therapeutic nihilism which at one time, under the malign influence of a former pope [illegible] to blight American medicine. [illegible] the book the paralyzing statement that pneumonia is a self-limited disease that cannot be [illegible] by therapeutic measures on the contrary, the author [illegible] that creosote has the power to [illegible] in a large percentage of cases and [illegible] almost all the remaining cases. This paragraph stamps the work as one to be [illegible] by those who recognize the responsibility which rests upon them to do what they can to [illegible] disease and are not content to know what it is that has brought their patients to the pitiable condition in which they are and what the pathological condition is that will kill them unless something is done to arrest its progress. It is truly appalling to think of the number of valuable lives that have been sacrificed to the do-nothing policy—called "expectant treatment"—eloquently advocated by some so-called "authorities" and followed by their unreasoning disciples. Dr. Wilcox has had the courage to speak out against the despairing teaching of those pessimists, and for this he deserves the gratitude of the 100,000 physicians and their 75,000,000 patients in this country. Throughout the book there is a note of hopefulness (for example, "taking all into consideration the treatment of pneumonia is especially satisfactory") which we cannot but feel marks the beginning of a new era in American medicine, one that will hit from it the opprobrium that it is powerless in the presence of the acute infectious diseases.

The general arrangement of the work is the same as that of the ordinary treatise on internal medicine, the usual sections under each heading being definition, etiology, pathology, symptoms, diagnosis, complications, prophylaxis, and treatment; but pathology, though treated of at sufficient length, is relegated to a subordinate place, instead of being made the principal section, and prophylaxis and treatment are accorded the position of honor. One curious slip, which will doubtless be corrected in the second edition, which, if the book meets with the reception it deserves, will soon be called for, is the spelling empyema. In these days of simplified spelling and vanishing digraphs, the insertion of an æ, where it never in any chance could belong, is unexpected and startling. The author retains the digraph in such words as ætiology, hæmorrhage, œdema, œsophagus, and anæmia; with this we have no quarrel, indeed we rather regret the loss of these etymological sign-posts in medical literature, but it is doing violence to the Greek language to transliterate *eta* by æ. But that is a digression. Dr. Wilcox's book is one that cannot be praised too highly; it has its faults—other than etymological—but it has virtues which far counterbalance its defects, and we unhesitatingly recommend it to the serious consideration of medical students and to practitioners, young and old, whose first and foremost desire it is to cure their patients. The pure scientist, whose only interest is to study the nature of disease, may consult works on pathology, of which there is no lack, or some of the one-time popular works on practice, so miscalled, but to the practical man, whose aim is to cure his patients, "The Treatment of Disease" will be found most helpful and inspiring.

Applied Materia Medica. A Text-Book intended for the use of Nurses in Hospital Training Schools. Based upon the U. S. Pharmacopœia eighth decennial revision, 1905. By J. Henry Schroeder, Ph.G., M.D., formerly Lecturer on Materia Medica in the Jewish Hospital Training School for Nurses, Cincinnati. Second Edition. Cincinnati: The Robert Clarke Company, 1907.

The nurse who uses this as her text-book will certainly not be overburdened with any unnecessary details of Materia Medica. The index contains no reference to castor oil, codliver oil, ammonia, Epsom salts, antiseptics, the making of solutions, and many other things that a nurse may reasonably be expected to know something about. As an introduction to the study of Materia Medica, the book may be useful to the nurse, and the author is to be congratulated that (in the words of the Preface) his book "has become the accepted standard in all Hospital Training Schools for Nurses where modern and progressive teaching methods prevail."

Paraffin in Surgery. By William F. Luckett, M.D., Attending Surgeon Harlem Hospital, and Frank I. Horn, M.D., Surgeon Mt. Sinai Hospital. New York: Surgery Publishing Company, 1907.

In a neatly printed monograph, the authors take up the history of paraffin in its application to clinical surgery, treat fully of the technique of its use, and refer to the accidents which have followed its employment. They find only six authentic cases of the latter—four of pulmonary embolus and two of amaurosis, from thrombosis of respectively the ophthalmic vein and the central artery of the retina.

Modern Medicine. Its Theory and Practice. In Original Contributions by American and Foreign Authors. Edited by William Osler, M.D., Regius Professor of Medicine in Oxford University, England; formerly Professor of Medicine in Johns Hopkins University, Baltimore; in the University of Pennsylvania, Philadelphia, and in McGill University, Montreal. Assisted by Thomas McCrae, M.D., Associate Professor of Medicine and Clinical Therapeutics in Johns Hopkins University, Baltimore. Volume I.—Evolution of Internal Medicine. Predisposition and Immunity. Diseases Caused by Physical, Chemical, and Organic Agents, by Vegetable Parasites, by Protozoa, by Animal Parasites, Nutrition, Constitutional Diseases. Philadelphia and New York: Lea Brothers & Co., 1907.

Although there are to be found those who are so thoroughly imbued with the modern spirit of ultraspecialism as to speak disparagingly of the encyclopedic systems of medicine or surgery, the real utility of such comprehensive works cannot justly be questioned, and the beneficent part played in the education of the profession at large by the great systems of the past more than justifies the attempt to duplicate the services they have rendered. It is with the greatest interest, therefore, that the progress of the present work will be watched both by those who are more nearly concerned in its pedagogical value by virtue of their connection with the schools, and by the great mass of practitioners who await its completion with the expectation of finding in it a guide, philosopher, and friend. The first volume to present itself before the medical public plays its part in a way that augurs well for the quality of those that are to follow. The scenario, so to speak, of the system has been skilfully devised so as to justify in almost dramatic fashion the right of the work to its title, for the subjects appearing in the inaugural instalment are well adapted to impress the reader with the ultramodernity of the subject matter. The chapters on the zoology of the protozoa, mosquitos, and venomous snakes should convey sufficient evidence of the far reaching ramifications of the medicine of to-day, while the perusal of the sections devoted to the autointoxications and diseases of metabolism reveals the complete ascendency of organic chemistry—formerly a humble handmaiden in medicine, but now rapidly becoming a most exacting mistress. It is almost a foregone conclusion that under the experienced surveillance of so popular an author as Professor Osler the system will take a form suitable to its function of providing the average medical reader with the data necessary for the understanding of the pathology of disease, though it is to be hoped that the senior editor's notorious therapeutic nihilism will not influence the contributors to neglect the subject of treatment in accordance with the most approved modern practice. It would be nothing short of a calamity if the tendency of this work should prove to be in the direction of therapeutic pessimism.

The introductory chapter is an essay on the evolution of internal medicine, written in Dr. Osler's customary agreeable style. We must take exception, however, to the undue prominence which he gives to laboratory work to the neglect of therapeutics. Of course we would not decry laboratory work, for it has even now become almost indispensable to the up-to-date physician, but its chief value, we might indeed say its sole value, is in the indications for treatment which it furnishes. Concerning it Osler says: "Asked the single most powerful weapon to-day in the hands of the profession against quackery of all sorts, I would answer: the little laboratory room attached to the office of the general practitioner." It does not seem to have occurred to the writer of this illuminating sentence that quacks have flourished because they cured the sick, or at least relieved some of their symptoms and so persuaded them for the time being that they were cured. The death-knell of quackery will come when the scientific physician also cures his patients and is not content to fold his hands and mumble the shibboleth of the therapeutic nihilist, "Time is a self-limited disease." Dr. J. George Adami contributes a very valuable chapter on inheritance and immunity, and the three following chapters on diseases caused by light, x rays, electricity, air, heat, and cold are by Dr. Alfred Goodman. Dr. David L. Edsall has written three chapters on the diseases caused by chemical agents; poisons, opium, and cocaine are discussed by Dr. Alexander Lambert; food poisons by Dr. Frederick G. Novy, and snake poisons by Dr. Hideyo Noguchi. Two chapters of practical importance are those on the autointoxications by Dr. V. C. Vaughan, and Dr. J. H. Wright contributes two chapters on diseases due to vegetable parasites other than bacteria. The succeeding chapters on the various protozoal diseases are by Drs. Charles F. Craig, J. W. W. Stephens, David Thomas, and Richard Strong, the section including a chapter on the zoology of the protozoa by Dr. Gary N. Calkins, and one on mosquitos by Dr. L. O. Howard. The important topic of the diseases caused by animal parasites is the work of Dr. Charles W. Stiles, and Drs. R. H. Chittenden and L. B. Mendel have jointly produced the one on metabolism in health and disease. Diabetes mellitus and insipidus, and gout are discussed by Dr. Thos. B. Futcher, obesity has been allotted to Dr. Jos. M. Anders, rickets to Dr. George F. Still, and the volume closes with an article on scurvy by Dr. Robert Hutchinson. The publishers have provided paper of good texture and surface, agreeable type, and substantial binding.

The Harvey Lectures. Delivered under the Auspices of the Harvey Society of New York. 1905-6. By Prof. Hans Meyer, Prof. Carl von Noorden, Prof. Frederick G. Novy, Dr. P. A. Levene, Prof. W. H. Park, Prof. Lewellys F. Barker, Prof. Frederic S. Lee, Prof. Lafayette B. Mendel, Prof. T. H. Morgan, Prof. Charles S. Minot, Prof. J. Clarence Webster, Prof. Theobald Smith, Prof. W. H. Howell. Philadelphia and London: J. B. Lippincott Company, 1906.

Since the first public lecture under the auspices of the Harvey Society was delivered in the fall of 1905 these discourses have become a highly appreciated feature of the medical life of the city. The idea of having men eminent in different fields of medicine and the closely allied sciences, sum up in the course of a single lecture the most important standpoints of their respective branches for the benefit of those of their colleagues whose general or special work lay in other directions, has shown itself as practical and valuable in execution as it was admirable in conception. In a brief notice it would be impossible to refer adequately to any one of these brilliant dissertations, and the effort to present a detailed conspectus of their import must be abandoned. Suffice it to say that the volume represents a collection of what are in effect essays on some of the most important problems and conceptions of modern medicine, whose authors are masters of their subjects and who have succeeded admirably in rendering some of their special knowledge available to the many. The Harvey Society deserves the thanks of the profession at large for having organized such a series and for having made it possible for all medical readers to share the profits of the undertaking.

A Text-Book of Pharmacology and Some Allied Sciences. Therapeutics, Materia Medica, Pharmacy, Prescription Writing, Toxicology, etc., together with Outlines for Laboratory Work, Solubility and Dose Tables, etc. By Torald Sollmann, M.D., Professor of Pharmacology and Materia Medica in the Medical Department of Western Reserve University, Cleveland, Ohio. Second Edition, thoroughly revised and greatly enlarged. Philadelphia and London: W. B. Saunders Company, 1906.

The first edition of this well-known work has not only been thoroughly revised, but has been greatly enlarged, so that it has become a valuable reference book, while it still retains its value as a text-book for beginners in the study of medicine. Pharmacology proper has been treated in accordance with recent progress. The methods by which it is taught at the present time have necessitated elaboration of practical experimental methods. In this volume laboratory instruction and experimentation are made the basis of teaching, while the text itself is destined to play a distinctly subordinate part. As a result, the author has greatly extended his system of laboratory exercises, and outlines a very thorough course of instruction in which the student assumes, to a greater or less degree, the attitude of the original investigator. This series of experiments is in sufficient detail and is accompanied by such a comprehensive lot of explanatory notes as to assure a solid foundation of practical knowledge in this branch of medicine. The details of therapeutics are not considered.

Descriptions of technique and apparatus, as well as of chemicals, are sufficiently detailed for the needs of the beginner. Many additions which are of the utmost convenience are found, such as the dose table for animals, and the list of bibliographical references containing those most important for collateral reading, arranged both as regards subject matter and alphabetically.

The schematic outline of lessons emphasizing the most important drugs is of the greatest value. The Materia Medica has been revised according to the latest (the eighth) edition of the United States Pharmacopœia, as have the chapters on "Pharmacy" and "Assaying." Toxicology is treated in a general manner in one short chapter, the details being given under the heading of each drug. Complete tables for molecular weights, chemical formulæ, solubility, and dosage are given. The author's aim has been to present a text-book intended for both study and reference, and a thorough understanding of pharmacology is sought as a basis for the future teaching of clinical therapeutics.

Society Reports.

AMERICAN GASTROENTEROLOGICAL ASSOCIATION.

Tenth Annual Meeting, Held at Atlantic City, N. J., June 3 and 4, 1907.

Special Report to the MEDICAL RECORD.

Monday, June 3—First Day.

THE PRESIDENT, DR. H. W. BETTMANN OF CINCINNATI, IN THE CHAIR.

The Evolution of Gastroenterology.—Dr. BETTMANN delivered this opening address (see page 169).

Incomplete Forms of Exophthalmic Goiter in Relation to Gastrointestinal Disorders.—Dr. J. P. SAWYER of Cleveland, in this paper, said that gastrointestinal processes were intimately associated with vasomotor conditions. These in turn were markedly affected by the hyperthyroidism which at present was recognized in exophthalmic goiter. This hyperthyroidism existed in many cases which did not show the "cardinal signs." Routine examination of all cases for diagnostic recognition of disturbed vasomotor function due to this cause might show its existence in patients not having the symptoms of goiter of this type developed to such a degree that attention would be attracted to them in the course of an examination made without having that point in mind. It was thought to show, at least in the writer's vicinity, the greater prevalence of the disorder than was commonly noted; also, that therapeutic procedures based on special examination of stomach contents and feces might be considerably assisted by measures adopted to meet the recognized development of exophthalmic goiter. Among these measures were climate, hydrotherapy, electricity, and various drugs, including the antithyroidin of Moebius and thyroidectin. Special note was made of the effects of atmospheric conditions, particularly of relative humidity. Note was also made of certain blood findings.

Dr. A. L. BENEDICT of Buffalo said the thyroid gland was very unstable in its functions, and especially in young girls we found all kinds of disturbances, some with goiter, some without, and in all these cases the personal equation of the examiner must not be lost sight of. The speaker referred to the comparative frequency of thyroid disturbance, not only in gastroenterology but also in general practice.

Dr. J. A. LIGHTY of Pittsburg said he had used thyroidectin in a number of cases, with somewhat doubtful results. Those cases in which it apparently had most effect were young girls at about the age of beginning menstruation, with enlarged thyroids and evidences of hyperthyroidism. Many of these, doubtless, would have done equally well without the thyroidectin.

Dr. J. KAUFMANN of New York City referred to the profuse diarrhea which was at times the only pronounced symptom of an incomplete exophthalmic goiter, and said that instead of being due to vasomotor disturbance, as suggested by Dr. Sawyer, it was possible that it was the result of the toxins which were such a prominent factor of exophthalmic goiter, and which were perhaps excreted by the intestines. Based upon that idea, he had employed colon irrigations in these cases with good results.

Dr. SAWYER, in closing, said his experience with antithyroidin and thyroidectin had convinced him that their effect was positive, but less effective when used alone than when combined with physical measures, and in the treatment of such a case he would rather do without drugs than without the latter. The aim of the treatment should be the vasomotor control. With reference to the diarrhea, he regarded it largely as a vasomotor phenomenon, incidental to which was the production of these toxins in the body.

A New Blood Test.—Dr. MAX EINHORN of New York City made some remarks on this subject and demonstrated the method. (See Vol. 71, p. 937.)

Cases of True Intestinal Dyspepsia.—Dr. MAX EINHORN of New York read this paper. He stated that by the expression "intestinal dyspepsia" we understood conditions in which the digestive function of the intestinal tract was disturbed. It was advisable to distinguish two large groups of intestinal disturbances: (1) Those which concerned all three classes of food substances, namely, albuminates, carbohydrates, and fats—dyspepsia intestinalis universalis. (2) Those affecting only certain classes of foodstuffs—dyspepsia intestinalis partialis. This second group might be further subdivided according to the varieties of foods, the digestion of which was disturbed. These functional disturbances of the intestinal digestion might exist without appreciable anatomical change of the digestive apparatus, or they might be associated with lesions of that tract. The idea of testing the functions of the intestine in a similar manner as those of the stomach prevailed among clinicians for a long time, but its execution was attended with great difficulties. By means of the bead test, which Dr. Einhorn demonstrated at a meeting of the Association a year ago, an approximate estimate of the work of the intestine became possible. The method was easy to apply and the results were sharply defined. By a large number of examinations, the results of which would soon be published, he had become convinced that the digestive functions of the bowels might be well judged by means of this test, and he saw no reason why it should not be utilized in the study of diseases of the bowel. In using the bead test, if we found a substance in the beads undigested, it should not be taken for granted that no digestion whatsoever of such substance might occur in the bowel. That would be wrong, for the same foodstuffs in liquid form might still be well digested. We could only conclude from this test that there was a considerable diminution of the digestive power for those substances.

Dr. H. W. BETTMANN of Cincinnati said he had used these beads in some forty instances, and the conclusions he had derived from them were very similar to those of Dr. Einhorn. In a certain number of cases where he had employed them, only the potato substance was passed unchanged, indicating a carbohydrate intestinal indigestion. Because of the simplicity of the bead test suggested by Dr. Einhorn, it would probably eventually have a wide application.

The discussion was continued by Drs. A. L. Benedict of Buffalo and J. C. Johnson of Atlanta, and was closed by Dr. Einhorn.

Gastric Disturbances Caused by Hernia.—Dr. MAX BALLIN of Detroit, Mich., read this paper. He stated that any and every kind of hernia caused more or less gastric or intestinal trouble. The common large inguinal herniæ, if reducible, were responsible for flatulence, constipation, pain in the back and groin; if adherent, all these symptoms became more pronounced. Omental adhesions in a hernial sac could make a patient so miserable by loss of appetite and indigestion that serious loss of weight resulted, and there were cases of supposed malignant disease where afterward radical operation of the hernia relieved all the intestinal disorders. It should be borne in mind that if in a hernia any adhesions existed between the hernial sac and its contents, a truss would usually aggravate all the symptoms by pressure on the unreduced parts. Generally speaking, in adherent hernia, a truss was contraindicated. Wherever located, postoperative ruptures were most troublesome to the patient, but Dr. Ballin said that the main object of his paper was to call attention to intestinal disorders caused by small herniæ that were not easily discovered. Of these, he considered in detail four kinds, namely: (1) The so-called incomplete inguinal hernia; (2) the small femoral hernia; (3) umbilical hernia; (4) epigastric hernia, in or lateral to the linea alba, and peritoneal

lipoma. Under the latter heading he included hernia protruding in or close to the linea alba between the xiphoid process and the umbilicus. These hernia occurred very rarely below the umbilicus and were apparently due to congenital or acquired defects in the linea alba, although some claimed that loss of fat was an important factor in their etiology. Others claimed that just the opposite, adiposity, predisposed to such weakness, the fat replacing to some extent the resistant fibrous tissue. Epigastric hernia and lipoma might exist for many years without causing any symptoms. Then, suddenly, symptoms might arise, the chief one being pain. Usually these epigastric herniæ, on account of their size and the peculiar lipoma formation and adhesions, were not benefited by trusses and bandages, and a surgical operation was indicated. In conclusion, Dr. Ballin said that many cases of obscure abdominal trouble, marked by colic and vomiting, could be caused by hernia, and that it was very important to look in all such cases for small ruptures. These could be of any of the known varieties, but of special importance in producing gastric symptoms were the small epigastric herniæ and the peritoneal lipomas.

Dr. Max Einhorn of New York City said that according to his experience these herniæ, especially those of the epigastric variety, were very frequent indeed. He probably saw three or four every week, and he did not think that one half or even one-third gave rise to any symptoms. In the majority of these cases he ignored the hernia entirely, and considered it a mistake, sometimes, to even call the patient's attention to its existence.

Dr. J. A. Lichty of Pittsburg said he had seen only two cases of epigastric hernia, and in those two instances the patients did not complain of any symptoms referable to the hernia.

Dr. J. C. Johnson of Atlanta said that in a case of epigastric hernia which he saw recently the chief symptom was periodical attacks of pain. This was the only case of epigastric hernia he could recall among several thousand examinations.

Dr. G. W. McCaskey of Fort Wayne said he was greatly astonished at the frequency with which Dr. Einhorn met with cases of epigastric hernia.

Dr. Charles D. Aaron of Detroit said a case of epigastric hernia which he reported ten years ago was that of a man who had been an invalid practically for fifteen years because of an epigastric hernia about the size of a marble, with an opening into the linea alba scarcely larger than the point of a pencil. He was completely relieved by an operation. These cases were not the kind where the opening was large enough to admit even the finger tip, and replacement was impossible.

Dr. J. Kaufmann of New York City thought there were cases of epigastric hernia which gave rise to serious trouble, and which could not be cured by putting the patients to bed. In any case that was giving rise to symptoms he would certainly advise an operation.

The discussion was continued by Drs. J. Fuhs of Brooklyn and G. W. McCaskey of Fort Wayne, and was then closed by Dr. Ballin.

The Gases of the Intestine, with Demonstration of an Original Apparatus for the Collection and Analysis of Stomach and Intestinal Gases.—By Dr. S. Basch of New York. The author stated that the study of the intestinal gases possessed interest mainly as a physiological and clinical problem, but the important role which they played in a number of abnormal conditions clothed them, especially, with more than theoretical interest. As was well known, the intestinal tract, after the very first ingestion of food, was never entirely free from gases. Throughout life there was a constant cycle of production and elimination. Under healthy conditions this balance of interchange proceeded without discomfort or marked disturbance, but if for any cause there was a derangement of its equilibrium, flatulence, borborygmi, meteorism, tympanites, and other conditions, varying in their significance from the merest discomfort to the severest gravity, might result. It was formerly held that the greater portion of the intestinal gases passed off per anum. This view was now known to have been erroneous, and it was conceded that in the healthy individual at least as much disappeared through absorption into the blood and expulsion by the respiratory tract. Under a mixed diet, the prevailing gas formed in the intestine was CO_2. The amount, naturally, was larger under a heavy than under a light form of diet. CO_2 being a product of fermentation, was most abundantly evolved in the earlier stages of both intestinal and fecal fermentation, while the hydrocarbon series, being the result of putrefactive decomposition, developed, in general, later. H_2S also increased as the fermentative changes were replaced by the putrefactive: It could not be quantitatively determined in these gas mixtures, but its presence was demonstrated by exposing strips of filter paper soaked with lead acetate solution to the gas.

Dr. S. J. Meltzer of New York City said that in view of the present tendency to ascribe a lot of trouble to the faulty digestion of proteids, it would be interesting to learn in what proportion the intestinal gases varied when the patient was on a proteid or carbohydrate diet.

Dr. S. Basch of New York City, in closing, said it had been shown that the carbohydrates were largely responsible for the production of carbonic acid gas, while the proteids were responsible for the production of marsh gas, ammonia, and putrefactive gases.

Lack of Gastric Mucus and Its Relation to Hyperacidity and to Gastric Ulcer.—Dr. J. Kaufmann of New York read this paper, in which he emphasized the fact that a lack of gastric mucus should be considered an unfavorable symptom, and that a diminished secretion of mucus and insufficient mucus covering deprived the gastric mucosa of its protection against all harmful influences, and particularly against the digestive activity of its own secretion. The routine examinations of stomach contents had heretofore been principally directed toward the study of the gastric juice and its disturbed secretion. A more careful study of the protective secretion of mucus and its disturbances should be systematically made. We were all familiar with the increase of mucus in certain gastric conditions, but too little attention had been paid so far to the decrease and the lack of secretion of gastric mucus. Dr. Kaufmann said his observations during recent years had convinced him that decrease and lack of secretion of gastric mucus was of frequent occurrence, and played an important rôle in the pathology of diseases of the stomach.

Dr. Max Einhorn of New York City said there were conditions under which there was certainly a diminished secretion of gastric mucus, and this was very frequently met with in achylia gastrica. In fact, it was very rare to find any mucus present in achylia gastrica. In that affection there was an absence of everything; there was no mucus nor gastric juice, and the food passed through the stomach unchanged.

Dr. S. J. Meltzer of New York City said the gastric mucus acted mechanically as a protective, in which function it was perhaps assisted by some chemical action. Foster had recently shown that mucus was capable of combining with hydrochloric acid.

Dr. J. C. Johnson of Atlanta said that clinically he had found that patients who complained of certain definite symptoms, accompanied by excessive hydrochloric acid and mucus, would be relieved of their symptoms with the removal of the excessive mucus. The speaker expressed the opinion that the question as to the possible protective value of the gastric mucus was still *sub judice*.

The discussion was continued by Drs. F. B. Turck of Chicago and G. W. McCaskey of Fort Wayne, and was closed by Dr. Kaufmann.

Demonstration of a Method of Estimating Percentage of Proteids, Fats and Carbohydrates in Food.—

By Prof. Irving Fisher of New Haven. In connection with this demonstration, the speaker stated that there had been previously two methods in use for estimating the proteids, fats, and carbohydrates in foods, which might be distinguished as the method of weight per cent. and the method of calories per ounce. By the first method, the weight of each food is multiplied by the percentage of weight of proteid, fat, or carbohydrate which it contains. The products give the weights of the three elements. The total calories were then found by multiplying these weights by the food value of proteids, fats, and carbohydrates per gram, and adding the results. This method was too laborious to be of much practical service to physicians. In the second method, a table was prepared expressing in calories the proteids, fats, and carbohydrates in an ounce of each given food. This method had the advantage that the proteids, fats, and carbohydrates and total fuel value were all measured in the same units, namely, calories. A simpler method than either of the preceding was to form a table giving the per cent. of total calories in the form of proteid, fat, and carbohydrate. This method had the advantage of being easily visualized by graphic representation, and of lending itself to quick computation by means of a mechanical diet indicator.

Dr. A. L. Benedict of Buffalo said Professor Fisher's demonstration had given a very clear illustration of what small quantities of food the average adult really required, and how much we ate in excess of that amount. To verify that fact, one had only to observe the average diner at his hotel table, where even in the bread and butter that he munched before his meal, and the olives he consumed between the courses, and the fruit and nuts and ice cream he took for desert, he had eaten more than his daily ration of calories.

Study of Urinary Acidity.—Dr. A. L. Benedict of Buffalo read a paper on this subject, in which he reported in detail his clinical deductions from a study of the urinary acidity. He was unable to verify the observation that there was an alkaline and an acid tide in the urine in the course of digestion, nor was he able to verify the observation in patients that rheumatism was associated with superacidity. In acute articular rheumatism, the acidity was not as high as we should expect. In numerous observations of the urine he had rarely found it alkaline, nor had he found the decrease in acid units after meals, as we should expect.

An Unusual Case of Ulcer of the Stomach.—By Drs. J. M. T. Finney and J. Friedenwald of Baltimore. In this case the clinical diagnosis of gastric ulcer was made, which was confirmed by the gross findings in the laboratory and subsequently by the microscope. At the operation a markedly indurated ulcer of the stomach was found, with enlarged glands in the mesentery. The case was thereupon regarded as one of cancer, and a gastrectomy was done, with the removal of a large portion of the stomach. The case was interesting from the fact that, notwithstanding the existence of a marked indurated ulcer in the stomach, the sympoms which were presented were by no means distinctive of that condition, and even upon direct inspection it could not be differentiated from carcinoma. The speaker emphasized the fact that all indurated ulcerations of doubtful character situated in the stomach should be regarded as carcinomatous, inasmuch as it is impossible in many of these cases to differentiate ulcers from carcinoma by simple inspection, and again, because in a certain number of these cases a carcinoma was apt to develop upon the indurated border of an old ulcer.

Dr. J. A. Lichty of Pittsburg said the case reported in this paper was very interesting on account of the fact that some enlarged glands were found in the mesentery. While he was aware of the fact that surgeons were inclined to consider these small enlarged glands in the mesentery as almost positive proof of a malignant condition, and a positive indication for a radical operation in cases which would formerly have been regarded as benign, he personally did not understand why these glandular enlargements should not be the result of an infection in the prescence of a good-sized gastric ulcer, and he was not convinced that they were necessarily an indication of a malignant condition.

Dr. J. Kaufmann of New York City said he had seen cases of gastric ulcer which caused enlargement and hardening of glands in the mesentery, and where a gastroenterostomy was performed and the future development of the case proved that the ulcer was of benign character.

Dr. G. W. McCaskey of Fort Wayne expressed the belief that every indurated ulcer of the stomach, after an exploration, should, if possible, be freely and liberally excised. The frequency with which cancer developed from an ulcer should not be lost sight of.

The Factors Concerned in the Healing of Peptic Ulcer.—By Dr. F. B. Turck of Chicago. The author premised his paper upon a reassertion of his former contention, based upon experiments on a large number of animals, that true peptic ulcer had for its most important factor certain alterations in the alimentary canal, with subsequent changes in the blood, characterized by diminution of the normal protective bodies, and that these etiological factors were general in character, and not local. The progressive microscopic picture revealed a process of breaking down—the cells themselves jagged and irregular in form, without round-cell infiltration; and a disintegrating and diminishing connective tissue structure. When the process of repair was instituted those cells capable of rehabilitation reasserted their physiological activity; those that had been injured beyond recall were carried away by a process of leucocytosis; new material for the formation of connective tissue was introduced, which progressively drew the edges of the ulcer together, acting in constricting bands. Hence the scar that remained. Similar factors that were active in the normal defense of the tissues were also concerned in the process of reconstruction. Processes of repair were impossible without restoration of the normal defenses of the blood.

Dr. Turck's paper was discussed by Drs. S. J. Meltzer of New York City and J. C. Hemmeter of Baltimore.

Demonstration of a Modification of the Boas Test for Blood in the Feces.—By Dr. A. L. Benedict of Buffalo. Gasoline was first added to the feces to extract the fats. Then old, ozenized oil of turpentine was added, and a fresh solution of guaiac. The test was just as delicate as the ordinary Boas' test, and a great deal simpler.

The Effect of Destruction of the Salivary Glands on the Gastric Secretion; a Possible Internal Secretion of the Salivary Glands.—By Dr. J. C. Hemmeter of Baltimore. The speaker stated that his attention was first attracted to this subject by the case of a woman who was suffering from septic parotitis which involved also the submaxillary and sublingual glands. Repeated examinations of the stomach contents in this case revealed an entire absence of hydrochloric acid and enzymes, with no proteolytic and no milk-curdling effect. Subsequently, the septic parotitis improved, and this was followed in turn by a restoration of the normal gastric juice. This case, Dr. Hemmeter said, brought to his mind the two cases of salivary gland disease and known as Mickulicz disease, which consisted of a bilateral induration of all the human salivary glands, resembling adenoma, and in which a chemical examination of the stomach contents showed this same deficit of hydrochloric acid and other gastric secretions. Influenced by a knowledge of these cases, the speaker said he undertook a series of experiments on three dogs with experimental accessory stomachs (Pawlow). After determining the proteolytic and milk-curdling power and the amount of hydrochloric acid in the secretion from the accessory stomachs of these animals, so as to learn what their gastric juice would accomplish under normal conditions, their salivary glands were removed. It was found comparatively easy to extirpate the submaxillary and sub-

lingual glands, but extirpation of the parotid was accomplished with great difficulty on account of the distance it extended backward underneath the skull. Still, even if a portion of the gland was left behind, its usefulness would be destroyed, providing its nerve and vascular connections were severed. It was found that extirpation of the submaxillary and sublingual glands had some deleterious effect on the gastric secretion, but after removal of the parotid the quantity of hydrochloric acid and the proteolytic power of the gastric juice gradually became less and less, until four or five days after the removal of the last portion of the salivary glands, the canine gastric juice no longer gave any evidence of hydrochloric acid, milk coagulating, or of proteolytic power, and the accessory pouch of the stomach secreted nothing but a serous liquid containing a trace of mucin. Upon removal of the accessory stomach there were no evidences of inflammation, and to all appearances the cells of the peptic ducts were normal. A second series of experiments was then undertaken. An esophageal fistula was produced upon a number of normal dogs, so that they could chew and swallow their food with apparent enjoyment. This food, however, was not permitted to enter the stomach, but was collected at the esophageal fistula and fed to other dogs who had been previously experimented upon by having their salivary glands removed, with consequent loss of gastric secretion. The introduction of this food into the stomach of these animals failed to excite any secretion of gastric juice. This experiment proved that the failure of gastric secretion after extirpation of the salivary glands was not due to absence of canine saliva, nor to lack of mastication. In order to corroborate these findings still further, the salivary glands of a number of healthy dogs that had been recently killed in the course of various experiments were obtained and ground up with quartz, and after a rather elaborate process a salivary extract was obtained free from proteid in the shape of a thick, opalescent, gelatinous liquid, which was injected into the superficial veins or peritoneal cavity of the dogs that had lost their power of normal gastric secretion after extirpation of their salivary glands. These injections were followed within one-half to two hours by such a resumption of the secretion of hydrochloric acid and ferments that the presence of gastric juice could be determined by the ordinary methods. This restoration was only temporary, however, lasting eight or ten hours, the period depending largely on the amount of the extract that was injected. It was also apparent that the injection of this salivary extract had a marked vasomotor influence, and the speaker said that in his efforts to produce a prolonged secretion of hydrochloric acid he sometimes injected too much, producing a surprising increase of blood pressure. When fed by the mouth, the extract had no effect on the secretion of hydrochloric acid. On the other hand, when injected, it was effective even after all the nerve supply of the stomach had been cut off. Dr. Hemmeter said he had not been able to isolate from this extract of the salivary glands the active principle, a substance like that obtained from the suprarenal gland. The speaker also referred to some experiments upon normal human subjects who were one day given a test meal which they were permitted to chew and swallow naturally, and the following day the identical test meal was poured into the stomach through a test tube. A chemical analysis of the gastric juice after the second method of feeding showed a considerable deficit of hydrochloric acid and enzymes. He also referred to Pawlow's psychic secretion. If a hungry dog even saw a piece of meat, it had the effect of exciting an immediate flow of gastric juice—the so-called psychic secretion (Pawlow) or *Appetitsaft*, which was brought about by the intermediation of nerves.

Dr. S. J. Meltzer of New York City said if Dr. Hemmeter's experiments could be verified, a new and interesting condition confronted us. The discovery of Bayliss and Starling established the fact that the secretion of the stomach produced in the duodenum a substance which they called secretin, and which stimulated the secretion of the pancreas. Now, Dr. Hemmeter found that a secretion of the salivary glands was essential to produce a secretion from the stomach. The substance Dr. Hemmeter found in the extract of the salivary glands apparently belonged to the group of bodies which Starling designated "hormones."

The discussion was continued by Dr. F. B. Turck of Chicago and Dr. J. C. Johnson of Atlanta, and was closed by Dr. Hemmeter.

Gastric Ulcer Complicated with the Symptoms of Cholelithiasis.—Dr. J. A. Lichty of Pittsburg read this paper, in which he offered the following conclusions: (1) The diagnosis of uncomplicated gastric ulcer should be made without difficulty. (2) When complications exist it may be impossible to form an exact opinion of the pathological condition in this region of the abdominal cavity before a laparotomy is done. (3) A careful and methodical anamnesis in these cases is of the utmost importance.

Dr. J. P. Sawyer of Cleveland said that for a number of years he had been following up a class of cases in which the symptoms at first were those of a catarrhal gastritis, and then, in the course of a few years, if not cured, they developed an infection of the gall-bladder or appendix, as shown at subsequent operation.

Therapeutics of Mineral Waters of the French Lick Type in Gastrointestinal Disorders.—Dr. G. D. Kahlo of Indianapolis read this paper, which contained his observations upon the therapeutic indications of alkaline-saline waters based upon a year's clinical experience at French Lick Springs, and the results of certain experiments made upon healthy subjects, together with a brief description of the water, and a general outline of the treatment. He had found the waters at the French Lick Springs especially valuable in gastric diseases, particularly after the abuse of alcohol, and equally favorable in hepatic disorders and hyperchlorhydria.

Dr. S. Basch of New York City said we had in the past made the mistake of sending too many of our patients abroad when we had so many excellent springs in our own country which compared very favorably with those in Europe. Unfortunately, at most of our springs there was a lack of proper attention to detail, not only in regard to the analysis of the waters, but also in regard to the general supervision of the springs. In Europe, the physicians who practised at such resorts were usually trained in physiology and body metabolism, while in this country that factor was almost entirely neglected. Furthermore, the patients were not kept under proper control. The hotels were usually on the American plan, and the patient did not attempt to restrict his appetite, and often drank the waters in unreasonable amounts. He thought the Association should interest itself in this important subject, and by arousing the proper interest, actual results could be obtained.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Stated Meeting, Held April 16, 1907.

Dr. Glentworth R. Butler in the Chair.

The Comparative Value of Clinical and Laboratory Diagnosis. (a) On the Clinical Side.—Dr. Edward E. Cornwall of Brooklyn read this paper. He said that it was perfectly obvious that diagnosis was an essential part of the practice of medicine, indeed was fundamental. It had been defined as active judgment applied to the problems of disease. It attained its object with the aid of two methods. The first of these, the clinical method, was summed up in bedside observation. It called into play the four senses of the physician—sight, touch, hearing, smell. It included not only examination of the patient, but also inspection of his discharges. The specula and various

other clinical contrivances were of valuable aid. This method reached its conclusion by the process of deduction. It was a slow and deliberate process. In striking contrast to this was the laboratory method, which was quick, precise, and scientific. It was noticeable that the younger physicians of to-day, notably the recent graduates, relied unduly on pathological reports and were less observant than the physicians of a generation ago. The recent graduate still had the glare of the laboratory in his eyes. For the majority of diseases, however, there was no laboratory aid. Moreover, in many diseases it was important and frequently necessary to make a clinical diagnosis before laboratory diagnosis could be called into requisition. In tuberculosis an early diagnosis was of the utmost importance; in the largest proportion of cases it was possible to make an early diagnosis by the clinical method alone. He who waited for the discovery of tubercle bacilli in the sputum frequently permitted the disease to advance beyond the stage of incipiency and become less amenable to cure. The absence of the Widal reaction in typhoid fever, in the face of undoubted clinical symptoms, had very little value. In diphtheria undue reliance was not to be given to the presence or absence of the Klebs-Löffler bacilli in the throat. As Sahli observed, the physician who relied entirely on the cultural report was frequently deceived. There were cases of diphtheria during the course of which ordinary cultures did not reveal the presence of the characteristic bacilli. On the other hand, in many cases of follicular tonsilitis the bacilli were obtained from the throat. In these cases the bacilli played the rôle of passive "bystanders." In the early stages of chronic nephritis, when treatment was peculiarly available, it was possible to make a diagnosis, in some cases, even without the ordinary urinary evidences of the disease. A case presenting overaction of the heart, accentuation of the second pulmonic sound, and general increased tension in the arteries, without any other obvious cause, might be regarded, with just suspicion, as a case of nephritis, in the absence of the usual urinary changes. Such would subsequently reveal themselves. A case illustrating this point was cited. It was that of a lady thirty-five years of age, in whom occurred severe headaches, particularly coincident with the monthly flow, and in whom physical examination revealed a marked accentuation of the second pulmonic sound, with a blood pressure of 180 millimeters. Repeated examinations of the urine were negative. Finally a little albumin was discovered. In the case of malignant tumors laboratory reports were valuable, but they could not be trusted implicitly. Cases in which the pathologist made a diagnosis of benign tumor sometimes turned out to be malignant, and likewise cases which were characterized as malignant sometimes ran a benign course.

The Comparative Value of Clinical and Laboratory Diagnosis. (b) On the Laboratory Side.—Dr. GEORGE LAMB BUIST of Brooklyn read this paper. He declared that the clinical methods formed the basis of the art of diagnosis. He guarded against overestimating the value of laboratory diagnosis, and placed it where it truly belonged, as a valuable aid to the clinical diagnosis. The laboratory diagnosis furnished one of the symptoms in the clinical picture. The laboratory methods had their limitations. A reactionary attitude against them had been lately discernible. Too much had been expected of the pathologist. Pathological findings had to be considered in the light of the clinical symptoms. It was suggested that in many instances the pathologist knew too little about the facts of the case. It was desirable that the pathologist should more frequently visit the bed of the clinician and that the clinician should more frequently visit the bench of the pathologist. The speaker urged the importance of having in all hospitals a paid resident pathologist. The vocation of the professional pathologist was to be encouraged by more frequent patronage by the general practitioner. It was important that the latter should know how to prepare specimens properly for the pathologist. The addition of a few grains of thymol to a specimen of urine, preserved this indefinitely, and prevented disintegration of the casts. Sputum over twenty-four hours old was not good for examination, bloody sputum was markedly hemolytic. There was a positive value in the laboratory findings in the leukemias and anemias. The value of leucocytosis in diagnosis and prognosis was alluded to.

The Diagnosis and Treatment of Cardio-Vascular Renal Disease.—Dr. JAMES TYSON of Philadelphia, Pa., read this paper. He said that the need of the term was evident; the condition was of frequent occurrence, and the difficulties in recognizing its invasion and in its treatment were considerable. Bright was the first to recognize this condition. In a certain number of cases there was hypertrophy of the heart with thickening and hardening of the arteries. This arteriosclerosis occurred in two forms—a diffuse and a localized variety. To the diffuse variety the term angiosclerosis was applied. A satisfactory explanation of the cause of this condition was not yet vouchsafed. Bright attributed the thickening of the arteries and the hypertrophy of the heart to the altered quality of the blood due to the retention of toxic substances from failure of renal elimination. Sir George Johnson maintained that the thickening of the arteries was mainly muscular, and that this was the result of an attempt on the part of the arterioles to prevent impure blood from reaching the tissues, and owing to the increased peripheral resistance produced by the muscular spasm the general blood pressure was raised and the heart hypertrophied. In 1877 Ewald suggested increased viscosity of the blood as the cause of arteriosclerosis. As similarly maintained later by Clifford Allbut, an increased viscosity of the blood resulting from vicious habits of diet and exercise, caused an increased difficulty in the capillary circulation, an increased blood pressure, and vascular degenerative processes due to this overstrain. Thoma asserted that whenever from any cause slowing of the blood current took place the lumen of the vessel became narrowed so as to insure the maintenance of the normal rate of blood-flow. The cause of the initial slowing was attributed either to a primary weakening of the media and consequent dilatation of the vessels, or to an increased resistance in the peripheral vessels. The recent work of Pierce and Stanton on experimental arteriosclerosis showed that the hypertrophied changes in the media were really a reparative process to compensate for the weakening of the media due to the ingestion of poisons. The speaker referred to the arteriosclerosis associated with diabetes mellitus, syphilis, gout, overfeeding, alcoholism, and overexertion associated with alcoholism. Arteriosclerosis was almost invariably associated with hypertrophy of the left ventricle. The latter was an effort to compensate for the increased tension in the arteries. Nervous strain was frequently a cause of high tension, and therefore of arteriosclerosis. Stengel had recently alluded to the association of arteriosclerosis with neurasthenia and shock. Hereditary influence also played an important rôle. O. T. Osborne had attributed high tension in the arteries to the effect of the internal secretions—particularly those of the thyroid and suprarenal glands. In a series of 156 cases of nephritis N. B. Potter found hypertrophy of the left ventricle in 30 per cent., and arteriosclerosis in 22 per cent. In cardiovascular renal disease, which was the name given by the speaker to the peculiar association of nephritis, arterial thickening, and hypertrophy of the left ventricle, it was noted that cardiac murmurs were conspicuous by their absence; their presence had to be accounted for by some other cause than renal disease. In 1872 Gull and Sutton referred to the frequent association of renal and arterial diseases, and maintained that the lesions in the kidney were a part of the general fibrous overgrowth—that the morbid condition in the arterioles and capillaries was the primary and essential condition of Bright's disease. The speaker believed that this was the case in old persons. But he still believed that there were many cases of arteriosclerosis

secondary to renal involvement. Albumin and casts appeared earlier in the cases of primary renal disease. In general arteriosclerosis there frequently occurred transitory symptoms of vertigo, tinnitus aurium, amaurosis, etc. Where renal disease was associated more serious and permanent conditions were found. The renal disease was either primary or it was a part of general arteriosclerosis. In both cases the heart was hypertrophied. If a murmur was present it was probably a primary disease of the heart. The prognosis was favorable if the heart disease was primary. The treatment of cardiovascular renal disease included a restriction of diet and a prohibition of overwork. Drugs were to be given to counteract the contraction of the arteries. The iodides were useful for this purpose. The speaker referred to iodide of soda given in ten-grain doses twice a day and kept up continuously. Digitalis was not good. If the heart action was too powerful, tincture of aconite was useful. To produce dilatation of the arteries nitroglycerin in doses of 1/100 to 1/50 of a grain was good. In some cases rest in bed and a mild diet was necessary. In the primary heart cases liquids were to be restricted; if the patient was waterlogged and in danger of uremia he had to be purged and sweated.

The patient was to get two ounces of milk every two hours. With this treatment serious effusions frequently disappeared. In 1836 Bright advised incision of the legs. In chronic parenchymatous nephritis rest and diet were the same. Diuretics were useless. For its associated cardiac condition, digitalis and strophanthus were to be given in full doses of ten to fifteen minims of the tincture. Sparteine was valuable in doses of three-quarters to one grain every three hours. Citrates, tartrates, and acetates were indicated and were well borne. Purgatives were useful as an internal trocar. A useful drug was apocynum; apocynine was less irritating. The pill of digitalis, squill, and calomel was not to be forgotten.

THE WILLIAMSBURG MEDICAL SOCIETY.

Stated Meeting, Held April 8, 1907.

DR. LEON LOURIA IN THE CHAIR.

A Case of Cystic Degeneration of the Chorion.—Dr. ALEXANDER SPINGARN detailed the history of this case and presented the specimen. His excuse for drawing attention to this case depended not only on the extreme rarity of the condition, but also on the fact that the clinical history of his particular case presented facts of peculiar interest. The patient was a well-developed primipara, 22 years of age, married five months, and in the ninth week of gestation. The family history had been good, and, apart from the usual diseases of infancy and childhood, she had always enjoyed exceptionally good health. Almost from the very beginning of pregnancy she had experienced morning sickness and vomiting, and these had continued and become rather excessive until three days before delivery. Beginning with the third week of gestation, there had been a steady, slight, bloody discharge from the vagina, described by the patient as a spotting of the napkin with a liquid having the appearance of prune-juice. This had continued for five weeks, at the end of which time there had occurred profuse metrorrhagia, accompanied with sacral and abdominal pain. At this time, when first seen, she had shown no ill effects of her previous losses of blood. Her skin and mucous membranes had been of good color, and her pulse and temperature had been normal. Abdominal palpation revealed a uterus whose height was two-fingers' breadth above the symphysis. On vaginal examination the cervix was contracted, the uterus was slightly anteflexed, rounded and hard, fluctuation was absent, and no masses were felt at either side of or behind the uterus. The diagnosis of threatened abortion having been made, the patient was kept in bed, and the vagina was firmly packed with iodoform gauze. This was removed two days later. The bleeding and pains had ceased. The external os now admitted the finger-tip. Soon after the gauze had been removed vaginal bleeding again set in, and was accompanied with the discharge of minute, pinkish shreds. After a restless night, menorrhagia became severe and the sacralgia more marked. The patient had thus been bleeding, more or less profusely, for five days, after having merely stained the napkin for a period of five weeks. At 1 o'clock in the afternoon, after a severe attack of abdominal pain, she had suddenly become faint. She recovered in a few moments, and one hour later had a second and severe attack of syncope. Her vision had become dim and her limbs cold and numb. When the speaker arrived, one hour later, he found the patient in a condition of semiconsciousness, with pale skin and mucous membranes, and a pulse rapid and weak. There was no external bleeding sufficient to account for the profound shock. The uterus had enlarged quite perceptibly since the previous day, and had the size of a four months' pregnancy. With the aid of vigorous hypodermatic stimulation, the application of external warmth, and the Trendelenburg position, the patient gradually rallied. Morphine was administered. The symptoms had evidently been those of internal bleeding, and had been strongly suggestive of an ectopic pregnancy. But there was no tumor to be felt, nor was there any marked degree of abdominal tenderness. That evening the patient had a severe chill, which was followed by a rise of temperature to 104.4°. Early the following morning the latter had gone down to 98°, but a severe rigor occurred, after which the temperature rose rapidly to 103.4°. The same morning severe labor pains set in, and vaginal examination revealed a cervix sufficiently dilated to admit two fingers. A soft, slimy mass was felt in the canal of the cervix. When removed this had the appearance of boiled tapioca, revealing the characteristic vesicles of cystic degeneration of the chorion. The speaker determined to deliver the patient at once, and with his left hand pressing on the fundus uteri, and with two fingers of his right hand in the anterior fornix of the vagina pressing upward in the body of the uterus, he was able to squeeze the uterus between his two hands, and succeeded in delivering the entire ovum. This was about the size of a large orange, and was completely covered with the characteristic, pinkish, grape-like vesicles, suspended on pedicles. In the center of the mass was the blighted ovum, surrounded by its amnion, and having the size of a hen's egg. The delivery of the ovum was accompanied with the passage of a number of blood-clots and a moderate amount of bleeding. The body of the uterus remained hard and contracted, and no appreciable hemorrhage subsequently occurred. The temperature fell to normal the same day. The uterus rapidly underwent involution and the patient made a good convalescence, with no rise of temperature nor excessive bleeding.

Bronchoscopy, with a Demonstration of the Instruments Used and Their Application.—Dr. EMIL MAYER of the Borough of Manhattan read a paper with the above title. In connection with the paper he presented a half-dozen specimens of various foreign bodies that had been removed from bronchi of patients in the City of New York within the past year. These consisted of glass-headed pins, pieces of bone, a piece of copper, an orange seed, and a coin, the latter taken from the esophagus by means of the esophagoscope. The speaker stated that in the direct effect of life-saving from the result of inhalation of foreign bodies, the perfection of the bronchoscope was of enormous value, and that the profession was under lasting obligations to Professor Killian for his valuable aid in this direction. While from the very nature of things direct bronchoscopy must be always in the hands of those whose hands were trained to enter the larynx, and whose eyes had been accustomed to examinations through small apertures, yet it was incumbent upon the general physician to know what advances had been made in this particular field; for to the

latter would arise the question, upon the inhalation of a foreign body, how promptly should attempts be made at its extraction; and, secondly, should the extraction be performed with or without preliminary tracheotomy. To aid in the solution of these questions, the speaker stated, as a result of his experience, that foreign bodies of a plugging character should be promptly removed; metallic or other substances not occluding the bronchi might safely wait an opportune time. The removal of the foreign body was always to be attempted by way of the mouth and larynx, except in the case of very young children, whose larynges were too small for the introduction of the tube; here tracheotomy had to be performed and a large tube inserted. The endoscopic tube had served as an excellent substitute for the Killian. It was not alone for the removal of foreign bodies that bronchoscopy was useful, but also for its exceeding value as an added means in diagnosis. Among these were the endoscopic picture of the trachea and bronchi; the discovery of inflammatory processes, as in tuberculosis, syphilis, scleroma, lepra, stenosis following inflammation of the adjacent lymph glands, and tumors of the trachea and bronchi. Among the latter were the many needed examinations that were made in cases of goiter. The speaker concluded his remarks with a demonstration of the method of performing bronchoscopy, and of extracting foreign bodies with the aid of a phantom, and the Killian instruments and the Kierstein headlight for illumination.

Cerebrospinal Meningitis.—Dr. William Browning of Brooklyn read this paper. He referred to the constant sporadic character of this disease and its occasional epidemicity, resembling in this respect the ordinary run of infectious diseases of childhood. In Brooklyn, relative epidemics occurred in 1869, 1872, 1873, in the early '90s, and in the last couple of years. The bacteriology of the disease was discussed. There were a limited number of cases in which no organism whatever had been reported. It had been lately presumed that the meningococcus often disappeared after a little time, in some way, as a result of its own activity; but the trouble that it had already started continued, even to a fatal termination. The fluid obtained by lumbar puncture was always more or less turbid. Cytological examination of the fluid was, as a whole, so far not important, but the leucocyte count usually showed a marked increase. Rarely did the infection spread from person to person, only one case (that of a nurse contracting the disease) occurring in the speaker's experience. Outbreaks were prone to develop in the crowded quarters of ships, barracks, jails, and asylums. In Brooklyn the disease was more frequent along the water front. Indoor confinement, enforced by continued inclement weather, favored the development of the disease. The incidence of the infection was usually preceded by some inflammation about the upper air passages, which were becoming generally recognized as the usual avenue of infection. The onset was frequently sudden, with a chill, or only malaise. Convulsions, early coma, and high fever indicated a bad outlook. Other symptoms were headache, vomiting, rise in temperature, retraction of the head, and painful stiffness of the posterior neck muscles, which was perhaps the most distinctive of any of the symptoms; varying degrees of somnolence, all the way to coma; muscular spasms, tremors, and contractures; great lassitude, and subjective prostration; moaning or active delirium; slow pulse (at any rate, out of proportion to the temperature); tâche cérebrale, Kernig's sign, which indicated a hypertonicity of the muscles; a purpuric rash developing on the third day or later; photophobia; general hyperesthesia; strabismus, and various pupillary changes; occasional sudden deafness or blindness, and rapid emaciation. Differentiation from tuberculous meningitis was usually easy. There were many cases of meningismus and serous meningitis presenting all the symptoms of epidemic meningitis, occurring with special frequency in ear troubles, with a collection of sterile fluids somewhere in the middle of the brain, some of which recovered after supplying a vent to the fluid. The duration of epidemic meningitis was widely variable, and the mortality was probably 50 per cent. Sporadic cases and those occurring during the ebb of an epidemic were the more favorable. Some light cases were overlooked. Sequelæ, both direct and indirect, were numerous, the former including the acute early hydrocephalic distention recently described by Koplik. Convalescence was slow. In treatment, careful nursing was of importance. Neither theory nor practice warranted the icebag to the head and spine, and even the cold coil had a very limited value. Warmth to the surface below the neck was useful and rational, acting to draw blood to the surface and away from the intensely congested inner structures, reducing the intracranial pressure and soothing the irritated sensory organs. The hot packs were a good means of applying this treatment, but the best was by means of long sacks of stuffed dry bran, which could be laid along the lower extremities and up to the axillæ, and did not cause burns. Extreme peace and quiet were of the greatest value. The use of opiates was indicated—not merely the mild and rather depressant sedatives, as bromide, chloral, but the preparations and alkaloids of opium. The use of iodide of potassium had no special value in the acute stage, or against the infection itself; but it was valuable for the absorption of fluid and the relief of hydrocephalus. Lumbar puncture had a therapeutic as well as diagnostic scope. It was first introduced from Germany to this country by the speaker. Its indication was symptomatic, for the relief of injurious pressure due to accumulated fluid. The relief was often transient. The use of a special serum promised to help.

Pathological Society of Philadelphia.

At a stated meeting held June 13 Dr. Allen J. Smith exhibited a specimen of "Aneurysm of the Arch of the Aorta," with laceration of the inner coats of the dilatation, the formation of a dissecting aneurysm, and the escape of about 600 c.c. of blood into the pericardial sac. Adhesive pericarditis had resulted and the wall of the right ventricle had suffered a marked degree of fatty infiltration, almost wholly displacing the muscular structure of the ventricular wall. The specimen came from an elderly man who had been operated on about a year previously for cholelithiasis and a fistula of the gall-bladder had been permitted to remain. A diagnosis of carcinoma of the pancreas had been made and this was found after death to exist, together with the presence of a calculus in the common duct and another in the hepatic duct close to the liver. There had been no jaundice, and the contents of the duodenum were stained with bile, and bile also escaped through the fistulous opening. Dr. Smith exhibited also a specimen of "Daughter Echinococcus Cyst." The specimen came from a native American, who had been operated on and some 30 or 40 cysts evacuated from the mother cyst. Hooklets were not discovered in the contents of the cysts, but a scolex with its suckers in one of the daughter-cysts was visible. Dr. F. Hurst Maier presented a specimen of "Fibroid Uterus." One of the growths had undergone necrosis and the other hyaline degeneration. During life an offensive discharge had taken place, in addition to metrorrhagia, and the presence of malignant disease was suspected. Dr. W. T. Cummins exhibited a specimen of "Hypernephroma." The nature of the growth had been diagnosticated during life and no metastasis was discovered. The affected kidney was largely replaced by new growth, although the remains of the pelvis were still visible. Section disclosed the histological appearances of hypernephroma, and also the presence of a yellowish pigment, which it was thought might be adrenal secretion or perhaps modified blood-pigment. Drs. W. M. L. Coplin and R. C. Rosenberger described "Cases of Death from Poisoning by Emanations from Molds." Two men that

entered the hold of a steel vessel containing rags were fatally overcome and a third man who voluntarily went to their rescue was overcome but was resuscitated. This man stated that he had no sense of suffocation or of discomfort, and no air-hunger, but that he had an overwhelming desire to sleep. The rags were examined and found to contain no poisonous ingredient and likewise no pathogenic microorganism. The steel bottom and sides of the hold, however, were found to be lined with great masses of mold, which on culture on bread-paste yielded a growth of mold and microorganisms, which evolved a gas that proved fatal in 30 seconds for white mice. There was no evidence of the presence of carbon monoxide or carbon dioxide, and nothing of a positive character was learned from examination of the blood. Drs. J. N. Henry and R. C. Rosenberger read a paper entitled "A Case of Suppurative Cerebrospinal Meningitis Caused by the Typhoid Bacillus in Pure Culture, without the Customary Intestinal Lesions of Typhoid Fever," and they exhibited gross and microscopic specimens of cord and brain. The patient was a colored man who presented during life symptoms of cerebrospinal meningitis, with the presence of bacteria morphologically identical with the typhoid bacillus in the fluid obtained by lumbar puncture. After death the lesions of a purulent cerebrospinal meningitis were found, and in these, as well as in the blood, typhoid bacilli were demonstrated. There was an absence of the classical intestinal lesions of typhoid fever, although the mesenteric glands and also the spleen were slightly enlarged. Dr. D. Rivas presented a communication entitled "A Contribution to the Study of the *B. typhosus* and *B. coli communis* in Drinking Water." He pointed out the difficulty of detecting the typhoid bacillus in water and the significance of the bacterium coli as indicative of pollution. For the demonstration of the typhoid bacillus large quantities of water must be used and the culture medium must be of such a character as to favor rather than to inhibit the growth of the microorganism.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.*

Board of Medical Examiners, South Dakota.

January 9 and 10, 1907.

CHEMISTRY.

1. Define an atom, a molecule, chemical affinity, chemical action, atomic weight.
2. Phosphorus—state its source, enumerate its properties, and name some solvents.
3. What is the difference between a salt, an acid, and an acid salt? Give an example of each.
4. What is the ordinary source of glycerine? Give its formula. Write an equation showing the process of its preparation.
5. Give in detail your method of examination of urine for three abnormal constitutents, and state the clinical significance of each.

EYE, EAR, NOSE, AND THROAT.

1. Give symptoms and treatment in detail of lachrymal stricture.
2. Define mydriasis, myosis. Name some drugs which produce each condition. What is the Argyll-Robertson pupil? In what diseased condition is it found?
3. What are the diseases of the middle ear? Outline your treatment of any one disease. What complications are liable to occur?
4. Give symptoms and treatment of abscess of frontal sinus.
5. Define dysphagia, aphonia, dysphonia.

JURISPRUDENCE AND TOXICOLOGY.

1. How could you determine whether death was due to freezing or that the freezing had occurred after death, in a body found frozen?
2. Describe one or more chemical tests for blood that may be used in investigating suspected blood stains.
3. What is a "live birth," medicolegally? How would you determine whether a dead infant had lived or was "dead-born"?
4. What post-mortem appearances would indicate poisoning by phosphorus, arsenic, strychnine?
5. Give the symptoms, treatment, and post-mortem appearances of poisoning by carbolic acid.

PRACTICE AND THERAPEUTICS.

1. Differentiate toxic effects of strychnine and tetanus poison.
2. Diagnose bronchopneumonia.
3. Inform me on rheumatoid arthritis.
4. How can you make early diagnosis of tuberculous infection?
5. Mention two remedies which are used to check the secretion of milk.
6. Give symptoms and treatment of migraine.
7. Differentiate organic and functional heart murmur.
8. Give diagnosis, prognosis and management of aneurysm of the thoracic aorta.
9. Mention diseases in which the patellar reflex is exaggerated.
10. Differentiate scarlet fever and measles and suggest treatment for both.

PATHOLOGY.

1. Mention a few symptoms caused by toxins produced within the body.
2. Describe gliomata.
3. What do you understand "Wallerian degeneration" to signify?
4. What pathological conditions increase the elimination of urea?
5. Define hyperinosis, hydremia, melanemia, and hemoglobinemia.
6. Name some of the causes of active hyperemia.
7. What conditions give immunity from the pathogenic action of bacteria?
8. Amyloid degeneration—what do you know about it?
9. Give the pathology of locomotor ataxia.
10. What is embolism, a thrombus, an infarct?

PHYSIOLOGY.

1. Describe the functions of the kidneys, and name the products excreted.
2. Tell what you know about osmosis, and give examples of some.
3. What is color blindness, and what colors are usually indistinguishable to a person so affected?
4. What is the variation of temperature, in health, between childhood and old age, and how is the normal temperature of the body maintained?
5. Describe the normal heart sounds, and explain cause of same.
6. What is the cause of stammering and stuttering?
7. What diseases are usually quarantined, and for what length of time?
8. How many different kinds of blood corpuscles in the human body, and what are their relative numbers in health?
9. Name the active principles of the digestive secretions, and explain how each affects the food.
10. Name and describe the normal respiratory sounds of the lungs.

ANATOMY.

1. How many bones in the human body?
2. Describe the meibomian glands.
3. What muscles are attached to the great trochanter of the femur?
4. Describe the tibia, and state what bones it articulates with.
5. How many bones in the hand? Name them.
6. Name and describe the salivary glands.
7. Describe the mammary gland, and give nerve and blood supply.
8. Where is the popliteal space, and what structures are contained therein?

*It is proposed in this department to publish from time to time the examination papers of the various State Boards, in order that a candidate may become familiar with the character of the examination and so in some measure free himself in advance from the nervousness and dread which the unknown inspires. In furtherance of the same object answers to some of the questions will be published in order to show the candidate what the examiners expect of him. Not all the questions of all the papers will be so treated, for the answers to many, especially in the anatomical papers, are obvious or can be found in the index of any textbook on the subject; the answers to other questions, especially in the surgical papers, must sometimes be omitted because of the space they would demand. The candidate for a medical license will not find in these answers a short and easy road to success in the examination, for he is not likely to meet the same questions in the papers placed before him by the examiners. The object of publishing the questions and answers is only, as noted above, to acquaint the candidate with the general character of these examinations and to inspire him with confidence in the result of his trial.

9. What cavities may require tapping, and for what diseases, and at what points should the punctures be made?
10. What structures would be severed in an amputation at the middle of the humerus?

OBSTETRICS.

1. Describe the indications of pregnancy at the beginning of the third, sixth, and ninth months.
2. Name the principal diseases and conditions during pregnancy said to be caused by that condition.
3. Give causes, diagnosis, dangers, and treatment of antepartum hemorrhage. Also of postpartum hemorrhage.
4. In vertex presentation, after dilatation, how would you tell the position from internal examination alone? Describe a given case.
5. When during delivery would you use an anesthetic, and how? When is it contraindicated? Name your choice of anesthetic, with reason therefor.
6. What do you do to prevent laceration of the perineum?
7. Describe a well-marked case of puerperal sepsis, giving time of invasion, symptoms, course, and treatment.
8. How would you treat a shoulder presentation with arm down?
9. What is involution, and how long does it normally continue?
10. How, and how long would you treat a babe apparently dead when born?

DISEASES OF WOMEN.

1. Describe the preparation for, and the manner of opening and closing the abdominal wall in a laparotomy.
2. Describe a uterine curettement and its dangers. When should it be employed?
3. Differentiate simple from gonorrheal vaginitis, and give treatment for each.
4. Describe pruritus vulvæ, giving causes and treatment.
5. Describe a case of endometritis, and give treatment.

BACTERIOLOGY.

1. Define immunity. Explain (*a*) how acquired, (*b*) how destroyed.
2. Name the three most important culture media.
3. Give method of staining gonococci.
4. Give the cultural and microscopic points of difference between the *Bacillus coli communis*.
5. Explain the Widal reaction.

SURGERY.

1. Classify burns. Give methods of treatment.
2. What is shock? How would you treat the shock accompanying a severe injury of an extremity? State conditions under which amputation would or would not be justifiable.
3. In what manner may operative work be affected by (*a*) alcoholism, (*b*) leucocythemia, (*c*) diabetes, (*d*) atheroma, and (*e*) good health?
4. Mention the characteristic symptoms of fracture of the clavicle, and give a method of treatment.
5. Differentiate elbow joint injuries, and describe method of reduction and after-treatment of backward dislocation of this joint.
6. What are the causes of abscess of the frontal sinus? Outline its symptoms, treatment, and prognosis.
8. What is osteomyelitis? Mention the different varieties. Describe a case of acute infective osteomyelitis, giving briefly its causes, diagnosis, treatment, and prognosis.
9. What is an aneurysm? What are its predisposing and exciting causes, and the usual locations?
10. Give symptoms, diagnosis, and treatment of gastric ulcer.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS, SOUTH DAKOTA.

January 9 and 10, 1907.

CHEMISTRY.

1. An *atom* is the smallest quantity of an element that can enter into chemical action, or that can enter into the composition of a molecule.

A *molecule* is the smallest quantity of any substance (element or compound) that can exist in a free state.

Chemical affinity is the attraction that exists between atoms, whereby they are united to form molecules.

Chemical action is the action of one substance upon another whereby chemical change is produced.

Atomic weight is the weight of an atom of an element as compared with the weight of an atom of hydrogen.

2. PHOSPHORUS.—*Source*: From the phosphates. *Properties and solvents:* It is a solid, with a valence of three or five, an atomic weight of 31. The molecule consists of four atoms; it combines readily with oxygen and is an active reducing agent. It exists in four allotropic conditions—the yellow, red, black, and white varieties; the two former are the most frequently met with and have different physical properties, as follows: The *yellow* "when freshly prepared, and at ordinary temperatures, forms a yellowish, translucent solid, which, on exposure to light, becomes more darkly colored and opaque. It has the consistence of wax. When exposed to the air it gives off white fumes and an odor of garlic. At 32° F. it becomes brittle; at 111° F. it melts to a yellowish liquid, and at 554° F., in the absence of air, is converted into a colorless vapor. In air, at 140° F., it ignites, burning with a bright flame and giving off dense white fumes and producing ozone. In the dark this form of phosphorus gives off a peculiar pale light. It is insoluble in water, sparingly soluble in alcohol, ether, and the fatty and ethereal oils; very soluble in carbon disulfid, from which solution it separates in the form of crystals. This variety is exceedingly poisonous.

"The *red* variety is red, brown, or dark yellow in color. It may be heated to 482° F. without melting, but at that temperature it is suddenly converted into the yellow variety, which ignites with an explosion. It fires much less readily than yellow phosphorus, and may be kept dry, while the yellow must be preserved under water. It has no odor or taste, and is insoluble in those substances which dissolve the other form. It is not luminous at ordinary temperatures."—(Witthaus' *Essentials of Chemistry.*)

3. A *salt* is a substance formed by the substitution of an electro-positive element for part or all of the replaceable hydrogen of an acid.

An *acid* is a compound of an electro-negative element or radical with hydrogen, part or all of which hydrogen it can part with in exchange for an electro-positive element without the formation of a base.

An *acid salt* is a salt in which only part of the replaceable hydrogen of an acid has been replaced.

Examples: H_2SO_4 in an *acid;* Na_2SO_4 and $NaHSO_4$ are both *salts;* but $NaHSO_4$ is an *acid salt.*

4. Glycerin is obtained as a by-product in the manufacture of soap.

Its formula is $C_3H_5(OH)_3$, or $\begin{matrix} CH_2OH \\ | \\ CHOH \\ | \\ CH_2OH. \end{matrix}$

$$\left.\begin{matrix}(C_3H_5)'''\\(C_{18}H_{35}O)'_3\end{matrix}\right\}O_3 + 3\left\{\begin{matrix}K\\H\end{matrix}\right\}O = \left.\begin{matrix}(C_3H_5)'''\\H_3\end{matrix}\right\}O_3 + 3\left\{\begin{matrix}(C_{18}H_{35}O)'\\K\end{matrix}\right\}O$$

Tristearin. Potassium hydroxid. Glycerol. Potassium stearate.

5. To examine for *albumin:* "The urine must be perfectly clear. If not so, it is to be filtered, and, if this does not render it transparent, it is to be treated with a few drops of magnesia mixture, and again filtered.

"The reaction is then observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of nitric acid."

To examine for sugar: First remove any albumin that may be present, then "render the liquid strongly alkaline by addition of sodium carbonate. Divide about 6 c.c. of the alkaline liquid in two test-tubes. To one test-tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color."

To examine for indicanuria: "The urine is mixed with one-fifth of its volume of 20 per cent. solution of lead acetate and filtered. The filtrate is mixed with an equal volume of fuming hydrochloric acid containing 3:1000 of ferric chloride, a few drops of chloroform are added, and the mixture strongly shaken one to two minutes. With normal urine the chloroform remains colorless or almost so; but if an excess of indoxyl compounds be present the chloroform is colored blue, and the depth of the color is a rough indication of the degree of the excess."

Albumin is found in the urine: "(1) In fevers, as typhoid and pneumonia. (2) In valvular heart lesions, degeneration of the heart muscles, diseases of the coronary arteries, impeded pulmonary circulation, in pregnancy by pressure upon the renal veins, in intestinal catarrh and in Asiatic cholera. (3) In purpura, scurvy, leukemia, pernicious anemia, jaundice, diabetes and syphilis. (4) After taking Pb, Hg, I, P, As, Sb, chloroform, cantharides, oxalic, carbolic, salicylic or the mineral acids, turpentine and nitrates. (5) In large amounts in acute nephritis, and chronic parenchy-

matous nephritis; in small amount in chronic interstitial nephritis and amyloid kidney."

Sugar is found in urine as *"transitory glycosuria,"* "(1) in certain hepatic derangements, congestion, cirrhosis and amyloid degeneration; (2) in many diseases of the central nervous system, with tumors or hemorrhages at the base of the brain, in meningitis, concussion, fracture of cervical vertebræ, railway injuries, in epileptic and apoplectic seizures, and also in certain diseases of the peripheral nervous system, as in sciatica and in tetanus; (3) in acute febrile diseases, pneumonia, typhoid, acute articular rheumatism, scarlatina, etc., particularly during convalescence; (4) under the influence of many poisons, such as curare, chloral, carbon monoxide, morphine, arsenic, and the anesthetics. As *'permanent glycosuria'* (1) in lesions of the brain involving the floor of the fourth ventricle; and (2) in diabetes mellitus."

Indicanuria is found "in hypochlorhydria; in hyperchlorhydria of gastric ulcer; in conditions in which there is diminished peristalsis of the small intestines, as in ileus and peritonitis, not in simple constipation; also in conditions in which putrefactive changes occur in the body elsewhere than in the intestine, as in empyema, putrid bronchitis, gangrene of the lungs, etc." (From Witthaus' *Essentials of Chemistry.*)

EYE, EAR, NOSE, AND THROAT.

2. *Mydriasis* is the condition of extreme dilatation of the pupil of the eye.

Myosis is the condition of extreme contraction of the pupil of the eye.

Mydriatics: Atropine, homatropine, daturine, duboisine, hyoscyamine, cocaine.

Myotics: Eserine, pilocarpine, opium.

Argyll-Robertson pupil is the condition of the pupil in which it responds to accommodation, but not to light.

It is found in locomotor ataxia, general paralysis of the insane, and sometimes in cerebral syphilis.

4. *Abscess of frontal sinus.*—Symptoms: Intense frontal headache, which may become worse on lying down; pus may be discharged from the nose, chiefly on rising in the morning; pain on blowing the nose; the upper eyelid may be swollen; the mucous membrane of the middle turbinated bone will be found swollen and hyperemic.

Treatment: Establish free drainage; a spray of suprarenal extract will reduce the swollen and hyperemic mucous membrane; the anterior end of the middle turbinated bone may require removal, the frontal sinus may require to be opened and curetted. (And see below, SURGERY, Question 6.)

5. *Dysphagia* is painful or difficult swallowing.

Aphonia is loss of voice due to some peripheral lesion.

Dysphonia is an impairment of voice; or pain or difficulty in speaking.

JURISPRUDENCE AND TOXICOLOGY.

1. The post-mortem changes in death from freezing are not sufficiently characteristic to justify a positive opinion on the subject. But if the body were found putrefied, it would be evidence that death was not due to freezing, for intense cold hinders putrefaction. So, too, the posture of the body might afford some aid; if the body is found in a crouching posture, death was *probably* due to freezing, as that attitude is characteristic.

2. Let some of the stained material soak thoroughly in a very small quantity of saturated solution of sodium chloride. Put a few drops of the fluid on a slide, cover On cooling, hæmin crystals form, and can be seen under with a cover-glass, let evaporation occur, allow a drop of glacial acetic acid to enter from the side, and gently warm. On cooling, hæmin crystals form, and can be seen under the microscope.

3 To constitute a "live birth," there must be (1) complete extrusion of the child from its mother's body, and (2) some certain sign of life. The latter would be established by one or more of the following: pulsation of the cord, beating of the child's heart, motions of the limbs, twitchings of the muscles, wrinkling of the brows, puckering of the face, opening of the eyes, even if respiratica does not take place. (From Witthaus and Becker's *Medical Jurisprudence*, etc.)

PRACTICE AND THERAPEUTICS

1 In *strychnine poisoning* there is a history of taking strychnine; the symptoms develop rapidly; the spasms occur early; muscular symptoms commence in the extremities, and the muscles of the jaw become involved late, if at all; there is muscular relaxation between the convulsions.

In *tetanus* stiffness of the neck and muscles of the jaw with trismus of the masseters soon develop; risus sardonicus is present; the body is thrown into a condition of opisthotonos or emprosthotonos; the muscular rigidity is persistent, the paroxysms are very painful.

4 The early manifestations of pulmonary tuberculosis are: (1) *Physical signs*: Deficient chest expansion, the phthisical chest, slight dullness or impaired resonance over one apex, fine moist râles at end of inspiration, expiration prolonged or high pitched, breathing interrupted. (2) *Symptoms:* General weakness, lassitude, dyspnea on exertion, pallor, anorexia, loss of weight, slight fever, and night sweats, hemoptysis.

5. Two remedies to check the secretion of milk: belladonna, and potassium iodide.

7. *Organic murmurs* are due to stenosis or incompetency of one or more of the valves of the heart.

Functional murmurs are not due to valvular disease.

Organic murmurs may be systolic or diastolic; may be accompanied by marked dilatation or hypertrophy, and there will probably be a history of rheumatism or of some other disease capable of producing endocarditis. Whereas a murmur, usually systolic, soft, and blowing, heard best over the pulmonic area, associated with evidences of chlorosis or anemia, and affected by the position of the patient, is a *hemic* or *functional* murmur, and denotes as a rule an impoverished condition of the blood.

9. The patellar reflex is exaggerated in: hemiplegia, lateral sclerosis, general paresis, transverse myelitis, injuries to the spinal cord, hysteria, neurasthenia, tetanus, and strychnine poisoning.

PATHOLOGY.

1. Chills, malaise, fever, vomiting, and symptoms of general poisoning.

3. "Suppose a nerve is cut across, the piece of the nerve left in connection with the brain or spinal cord remains healthy both in structure and functions; but the peripheral piece of the nerve loses its functions and undergoes what is generally called after the discoverer of the process, *Wallerian degeneration.* A nerve is made up of nerve fibers, and each nerve fiber is essentially a branch of a nerve cell; when the nerve is cut the axis cylinders in the peripheral portion are separated from the cells of which they are branches and from which they have grown. These separated portions of the axis cylinders die, and the medullary sheath of each undergoes a gradual process of disintegration into droplets of myelin, which are ultimately absorbed and removed by the lymphatics. At the same time there is a multiplication of the nuclei of the primitive sheath. This degenerative process begins two or three days after the section has been made. In the case of the non-medullated fibers there is no medullary sheath to exhibit the disintegration changes just alluded to, and the nuclei of the sheath do not multiply; there is simply death of the axis cylinder. The degeneration occurs simultaneously throughout the whole extent of the nerve; it does not start from the section and travel to the periphery." (Kirkes' *Physiology.*)

4. The elimination of urea may be increased in: acute fevers and inflammations, diabetes, severe leukemia, paralysis agitans, pernicious anemia.

5. *Hyperinosis* means an excess of fibrin in the blood, *Hydremia* means an excess of the fluid constituents of the blood.

Melanemia means the presence of a black pigment in the blood.

Hemoglobinemia means the abnormal presence of hemoglobin in the plasma of the blood.

6. Active hyperemia may be caused by: stimulation of the vasomotor nerves, injury to the walls of the blood-vessels, sudden removal of support, the action of certain drugs.

7. See below, BACTERIOLOGY, Question 1.

PHYSIOLOGY.

3. Color-blindness is the inability to distinguish clearly differences of color. Red and green are the colors usually indistinguishable to a person so affected.

4. The variation of body temperature, in health, is very slight; it is maintained between 98° and 99° F.

The normal temperature of the body is *maintained* by the thermotactic centres in the brain and cord keeping an equilibrium between the heat gained or produced in the body and the heat lost. Heat is *gained* to the body by (1) the muscles, during contraction; (2) the secreting glands; (3) the brain, during mental activity; and (4) by the ingestion of food and hot liquids.

Heat is *lost* to the body by (1) the skin, through evaporation, radiation, and conduction; (2) the lungs; and (3) the excretions (feces and urine).

5. The *causes* producing the *first* sound of the heart are not definitely ascertained; the following are supposed to be causatory factors: (1) The vibration and closure of the auriculo-ventricular valves, (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall.

The *second* sound is caused by the vibration due to the closure of the semilunar valves.

6. Stammering and stuttering are due to a want of co-

ordination between the various groups of muscles concerned in the different actions that go to the make up of articulate speech. Imitation, adenoids, and fright are sometimes supposed to be contributing factors.

9.

DIGESTIVE SECRETION.	ACTIVE PRINCIPLE.	ACTION.
Saliva.....	Ptyalin.	Changes starches into dextrin and sugar.
Gastric juice.....	Pepsin.	Changes proteids into proteoses and peptones in an acid medium.
	A curdling ferment.	Curdles the casein of milk.
Pancreatic juice...	Trypsin.	Changes proteids into proteoses and peptones, and afterwards decomposes them into leucin and tyrosin; in an alkaline medium.
	Amylopsin.	Converts starches into maltose.
	Steapsin.	Emulsifies and saponifies fats.
	A curdling ferment.	Curdles the casein of milk.

ANATOMY.

9. (1) The *pleural cavity;* in the sixth or seventh intercostal space, midway between the axillary lines; or in the eighth intercostal space, near the angle of the scapula.

(2) The *peritoneal cavity;* on the semilunar line, or on the linea alba.

(3) The *pericardial cavity;* in the fifth left intercostal space, one inch from the sternum; or in the sixth left intercostal space, immediately to the edge of the sternum.

(4) The *subarachnoid space of the spinal cord;* in the middle line, between the fourth and fifth lumbar vertebræ.

(5) *Joints;* and (6) the *tunica vaginalis of the testis.*

10. Skin: fascia; muscles, biceps, coraco-brachialis, brachialis anticus, triceps; arteries, brachial, superior profunda, inferior profunda; veins, basilic, cephalic, brachial, superior profunda, inferior profunda; nerves, median, ulnar, musculo-spiral, internal cutaneous, musculo-cutaneous; bone, humerus.

OBSTETRICS.

9. By *involution* is meant the contraction and return of the uterus to its normal size after labor. It generally takes from six to eight weeks.

DISEASES OF WOMEN.

4. *Pruritus vulvæ* is a condition characterized by intense itching of the vulva and neighboring parts.

Pruritus vulvæ may be *caused* by:—parasites; diseases of the vulva, as inflammation, edema, vegetations, congestion, irritating discharges, lack of cleanliness, diabetic urine; it may also be of nervous origin, or idiopathic.

Treatment consists in removing the cause, if possible; cleanliness, fresh air, tonics, and general attention to hygiene; local applications of solution of bichloride of mercury, 1:2,000; or carbolic caid, 1:100; or lead and opium; dusting powders of bismuth subnitrate, calomel, or zinc oxide are also useful.

BACTERIOLOGY.

1. Immunity is the power of resistance of cells and tissues to the action of pathogenic bacteria.

(a) The conditions which give immunity from the pathogenic action of bacteria are:—(1) a previous attack of the disease; (2) inoculation, with small quantities of bacteria, so as to produce a mild attack of the disease; (3) vaccination; (4) the introduction of antitoxins; (5) the introduction of the toxins of the bacteria.

(b) Immunity can be destroyed by any condition which lowers the vitality of the tissues and thus causes lessened resistance to the action of the bacteria. Such are:—bad hygienic surroundings, exhaustion, exposure to cold, the action of poisons, diseases, injuries, etc.

2. Bouillon, gelatin, and blood serum.

3. The gonococcus stains with gentian-violet, and other basic aniline dyes; but it does not stain by the Gram method

4. The cultural and microscopic points of difference between the *Bacillus coli communis* and the *Bacillus typhosus* (of Eberth) are:

"(1) The motility of the colon bacillus is, as a rule, not very pronounced, sometimes absent; that of the typhoid bacillus is usually very active.

"(2) On gelatine plates the colon bacillus develops more rapidly and luxuriantly than the typhoid bacillus, and on potato it grows more abundantly, being almost always visible.

"(3) The colon bacillus coagulates milk with acid reaction within twenty-four to forty-eight hours; the typhoid bacillus does not coagulate milk.

"(4) The colon bacillus causes fermentation with production of gas in media containing sugar; the typhoid bacillus does not.

"(5) In nutrient agar or gelatine containing lactose and litmus tincture and of a slightly alkaline reaction, the color of the colonies of colon bacillus is pink and the surrounding medium red; while the colonies of typhoid bacillus are blue and there is little or no reddening of the medium.

"(6) The colon bacillus produces indol in cultures of bouillon or peptone; the typhoid bacillus does not.

"(7) When a twenty-four-hour-old bouillon culture of the colon bacillus is mixed with the blood or serum of a patient suffering from genuine typhoid fever, in a dilution of one to ten or more, after the first week of the disease, the Widal reaction is negative; cultures of the typhoid bacillus treated in the same manner and examined in the hanging drop give the characteristic agglutination and clumping of the bacilli." (*Reference Handbook of the Medical Sciences.*)

5. The Widal serum reaction "depends upon the fact that serum from the blood of one ill with typhoid fever, mixed with a recent culture, will cause the typhoid bacilli to lose their motility and gather in groups, the whole called 'clumping.' Three drops of blood are taken from the well-washed aseptic finger tip or lobe of the ear, and each lies by itself on a sterile slide, passed through a flame and cooled just before use; this slide may be wrapped in cotton and transported for examination at the laboratory. Here one drop is mixed with a large drop of sterile water, to redissolve it. A drop from the summit of this is then mixed with six drops of fresh broth culture of the bacillus (not over twenty-four hours old) on a sterile slide. From this a small drop of mingled culture and blood is placed in the middle of a sterile cover-glass, and this is inverted over a sterile hollow-ground slide and examined. . . . A positive reaction is obtained when all the bacilli present gather in one or two masses or clumps, and cease their rapid movement inside of twenty minutes." (From Thayer's *Pathology.*)

SURGERY.

2. Shock is the name given to a sudden and general depression of the vital powers due to some strong stimulation (such as injury or emotion) acting on the vital centers in the medulla, and producing vasomotor paralysis.

Treatment of shock:—place the patient in the recumbent position, with the head low, apply warmth to the body, administer a stimulant, and give a hot saline infusion; morphine, hypodermatically, may be necessary for the relief of pain.

Amputation may be done if it is necessary to save the patient's life, or if the damaged limb is adding to or prolonging the condition of shock. Some surgeons (*e.g.* Da Costa) think that it is never wise to amputate during shock; others (*e.g.* Roswell Park) oppose this view.

6. Abscess of Frontal Sinus.—"The usual cause is an injury which may long antedate the symptoms. This injury causes or leads to blocking of the infundibulum; secretion accumulates and distends the sinus; and in some cases pus forms. In many cases the fluid slowly accumulates, and it requires years to produce marked symptoms. In other cases infection takes place, and the symptoms are positive and violent. If the outlet into the nose is not permanently blocked the fluid may discharge itself from time to time. In the chronic cases there is rarely much pain. The chief sign is a swelling of the inner or upper part of the orbit, which swelling progressively increases in size and displaces the eye. If at any time acute symptoms supervene, there will be pulsatile pain, discoloration, and tenderness.

"*Treatment:* In some cases it is possible to pass a trocar upward from the nose into the sinus, and so drain and irrigate. In most cases an incision should be made through the soft parts, and the sinus opened by a trephine or chisel. After the sinus has been opened it must be curetted, the opening into the meatus should be restored and enlarged, and a drainage tube is to be passed from the forehead incision into the nostril. Some surgeons open the sinus by making an osteoplastic flap." (Da Costa's *Surgery.*)

Prognosis is generally good; some cases get well spontaneously, and most cases recover when the obstruction is removed and drainage is reestablished.

7. The lymphatic glands along Poupart's ligament are enlarged in syphilis; in malignant disease of the external

genitals; in boils or other sources of irritation around the anus and perineum.

8. Osteomyelitis is an inflammation of the medullary canal of a bone, including both bone and marrow.

Varieties: Simple acute osteomyelitis; acute infectious osteomyelitis; chronic osteomyelitis.

9. An aneurysm is a pulsating sac containing blood and communicating with the lumen of an artery.

Predisposing causes:—atheroma, syphilis, old age, arteritis, alcoholism, male sex.

Exciting causes:—increased blood pressure (which may be due to severe labor, sudden strains, violent exercise, chronic interstitial nephritis); injury to the artery, and embolus.

Usual locations:—Thoracic aorta, abdominal aorta, popliteal, femoral, carotid, subclavian, innominate, axillary, and iliac arteries.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Sept. 1-6
Arizona*	Ancil Martin, Phoenix	Phoenix	October 7
Arkansas*	F. T. Murphy, Brinkley	Little Rock	October 8
California	Chas. L. Tisdale, 1870 Sutter Street, San Francisco	San Francisco	August 6
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	October 1
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Nov'ber 12
Delaware	J. H. Wilson, Dover	Dover	Dec'ber 10
Dis. of Col'bia	W. C. Woodward, Washington	Washington	October 10
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	Nov'ber 20
Georgia	R. Anthony, Griffin	Atlanta	October 8
Idaho	J. L. Conant, Jr., Genesee	Boise	October 1
Illinois	J. A. Egan, Springfield	Chicago	
Indiana	W. T. Gott, 120 State House, Indianapolis	Indianapolis	October 22
Iowa	Louis A. Thomas, Des Moines	Des Moines	Sept'ber 17
Kansas	T. E. Raines, Concordia	Topeka	October 8
Kentucky*	J. N. McCormack, Bowling Green	Louisville	October 2
Louisiana	F. A. La Rue, 211 Camp Street, New Orleans	New Orleans	October 15
Maine	Wm. J. Maybury, Saco	Portland	Nov'ber 12
Maryland	J. McP. Scott, Hagerstown	Baltimore	Dec'ber 3
Massachusetts*	E. B. Harvey, State House, Boston	Boston	Sept'ber 10
Michigan	B. D. Harrison, 205 Whitney Building, Detroit	Lansing	October 8
Minnesota	W. S. Fullerton, St. Paul	St. Paul	October 1
Mississippi	J. F. Hunter, Jackson	Jackson	October 8
Missouri	J. A. B. Adcock, Warrensb'g	St. Louis	Sept'ber 10
Montana*	Wm. C. Riddell, Helena	Helena	October 1
Nebraska	Geo. H. Brash, Beatrice	Lincoln	August 7
Nevada	S. Lee, Carson City	Carson City	August 5
N. Hampshire*	Henry C. Morrison, State Library, Concord	Concord	January 14
New Jersey	J. W. Bennett, Long Branch	Trenton	October 22
New Mexico	B. D. Black, Las Vegas	Santa Fe	Dec'ber 2
New York	C. F. Wheelock, Univ. of State of New York, Albany	New York, Albany, Syracuse, Buffalo	October 1
N. Carolina*	G. T. Sikes, Grissom	Winston, Salem	May 1908
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks	October 1
Ohio	Geo. H. Matson, Columbus	Columbus	Dec'ber 10
Oklahoma*	J. W. Baker, Enid	Guthrie	Sept'ber 24
Oregon	B. E. Miller, Portland	Portland	
Pennsylvania	N. C. Schaeffer, Harrisburg	Philadelphia, Pittsburg	Dec'ber —

Wyoming	S. B. Miller, Laramie	Laramie	Oct. 9

* No Reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Iowa.—The State Board of Medical Examiners issues two forms of reciprocal certificates: 1. Upon the basis of a written examination by a State examining board having reciprocal relations with the Iowa board; provided that the general average attained by the applicant was not below 75 per cent. The following States have been admitted under this reciprocity: Colorado, Illinois, New Jersey, North Dakota, Ohio, South Dakota, Virginia, Wyoming. 2. Upon a certificate issued by another State holding reciprocal relations with Iowa upon the basis of a diploma without examination; provided such diploma was issued prior to January 1, 1899, by a medical college recognized by the Iowa State Board of Medical Examiners, as in good standing when said diploma was issued. The following States have been admitted under this reciprocity: Georgia, Indiana, Kansas, Kentucky, Maine, Maryland, Michigan, Minnesota, Nebraska, Nevada, North Carolina, South Carolina, Wisconsin.

South Dakota has decided to discontinue reciprocity.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending July 27, 1907:

	Cases	Deaths
Tuberculosis Pulmonalis	346	143
Diphtheria	278	30
Measles	401	24
Scarlet Fever	180	14
Smallpox	1	1
Varicella	20	..
Typhoid Fever	81	14
Whooping Cough	47	10
Cerebrospinal Meningitis	20	8
Malarial Fever	.....	.....
Totals	1374	244

Helath Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended July 19, 1907:

SOME PLAIN TRUTHS ABOUT SYPHILIS.*

By L. DUNCAN BULKLEY, M.D.,

NEW YORK.

PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL, CONSULTING PHYSICIAN TO THE NEW YORK HOSPITAL, ETC.

When your courteous and able President selected this topic, and asked me to bring the subject before you, I felt somewhat embarrassed for several reasons. First, syphilis has been so thoroughly studied that I could not hope to present anything very new; and second, the subject is such a very large one that it would be difficult to compress into the allotted time the consideration of such plain truths as it might be of interest and value to recall.

But, as this is an association of practitioners in the various branches of medicine I concluded that he wished me to present the subject of syphilis in a practical way, emphasizing such points, which are plain truths, as may be of service in the recognition and treatment of the malady. For although much may be known about any disease, a certain gain is often had by reviewing our knowledge and crystallizing our views concerning it. It is with this aim that I shall attempt to address you this evening, bringing what I can of clearness of vision from one who is in daily contact with syphilis to some, perhaps, who meet with it comparatively seldom.

The first plain truth which I would bring forward is that syphilis is a much more common disease than is generally thought to be the case, not infrequent even in good circles of society, both in the city and country. Statistics may, of course, be misleading, and naturally vary very much with the class of practice from which they are taken; but as syphilis invariably affects the skin at some time during its course, the statistics taken from dermatological practice probably afford a more correct indication of its relative frequency than those from any other branch of practice. Now, of several hundred thousands of cases of miscellaneous diseases of the skin compiled from the practice of members of the American Dermatological Association, from various cities all over the United States, syphilis always figures as a causative agent in about 10 per cent., or even more, of the cases, while eczema forms from 25 to 30 per cent. In my own published statistics of 20,000 personal dermatological cases, in public and private practice, syphilis formed over 12 per cent. of all. Did time permit I could cite scores of cases where the disease had been unrecognized and neglected for a long period of time, in private practice both in cities and rural districts.

The next plain truth is the now well recognized fact that syphilis is not necessarily a venereal disease and that its existence in an individual by no means carries with it necessarily any stigma, or imputation of immoral or impure conduct; although, of course, in the very large share of cases the disease is undoubtedly contracted in illicit intercourse. "Syphilis in the innocent" is no longer a by-word, but the thousands of cases on record where the disease was acquired in as thoroughly an innocent a manner as tuberculosis, have placed the subject of its control or prevention by public measures on quite a different basis from that commonly considered some years ago.

It will probably never be possible to state accurately just the proportion of cases in which the disease is innocently acquired, as this proportion must vary greatly according to the standpoint and opportunities of different clinicians; but to those who are not very familiar with the literature of the subject it may be surprising and instructive to know to what extent this has been recorded by reliable observers.

From a study of syphilis observed in private practice Fournier stated that nearly 25 per cent. of the females contracted the disease innocently and undeservedly, while among the *married females* the disease was unmistakably traced to the husband in 75 per cent. of all cases; in discussing Fournier's paper, Ricord stated that the matter had not been at all exaggerated, but that he himself had met with fully the same percentage.* My own statistics present even a much larger proportion of innocent syphilis in females, in private practice, indeed a careful study and analysis of my cases shows that in somewhere near 50 per cent. the disease was acquired in a perfectly innocent manner, wholly apart from sexual transgression. This large proportion in females is, of course, made up mainly of cases of marital syphilis, where the wife contracts syphilis from the husband, who was infected before or after marriage, with also the not inconsiderable number of cases where innocent girls acquire chancre of the lip or mouth by kissing their fiancées, of which I have seen many, many instances; indeed in my statistics there were 50 per cent. more cases of chancre of the lip in females than in males.

But innocent syphilis is also not at all infrequent among males, and in the better classes of society, at least, this is true of from 5 to 10 per cent. of all cases, as has been repeatedly stated; finally, extragenital chancres are really much more common in both sexes than is commonly recognized.

Time does not permit us to enter largely into the subject of extragenital chancres, but the caution must be given not to overlook this source of infection when there is reason to believe that

*Read before the Medical Association of the Greater City of New York, May 20, 1907.

*Bulkley: Syphilis in the Innocent. New York, 1894. Pp. 28, 197.

syphilis is present and yet when there is no suspicion of venereal contagion. The modes and methods of innocent infection are so many, and often so unexpected and surprising, and the forms and appearances of extragenital chancres are so varied and often puzzling, that it is frequently a very difficult task to unravel the mystery of syphilitic inoculation; but with sufficient care and patience this can be done, and in many a case an otherwise distressing stigma can be lifted from an innocent person.

Another plain truth in regard to syphilis is that, certainly in its earlier stages, it is a contagious affection, in regard to which too much care cannot be exercised in order to prevent the infection of others, innocently or otherwise. Unfortunately we are not in a position to state with positiveness how long the contagious period of syphilis lasts, for of late years there has been more or less evidence produced that even the gumma, which commonly belongs to the later stages of the disease, is contagious. We know, however, that during the first year, or possibly two, there is great likelihood of the occurrence of moist lesions, principally on the mucous surface, which give off a virulent contagion, and that even the briefest contact with such, or the smallest amount of poisonous matter transferred on any object, can communicate the disease through an abraded surface.

When syphilis is under perfect medical control there is much less danger of the occurrence of these contagious lesions, but in neglected cases there is undoubtedly possibility of contagion even for many years. Great is the responsibility of the physician, therefore, who has the care of an individual with syphilis, that he may so impress these dangers upon the patient that the disease shall spread no further. It is strange indeed that in these enlightened days, especially since the more or less successful crusade against tuberculosis, there has not been the slightest attention paid to syphilis, which counts its victims by thousands, with untold danger to health and life. It would be interesting, did time permit, to bring to your attention some of the ravages which have been produced by syphilis, in years past, in the great and small epidemics of this disease which have occurred in remote districts, principally in Europe; and it would be instructive to recall how quickly these have been stamped out when once the real nature of the trouble was recognized and proper medical and sanitary precautions taken. As I have remarked often before, the great contagious disease syphilis has been *ignored* through *ignorance,* and *neglected* through *negligence.*

Another plain truth regarding the disease under consideration is that it is really a serious affection, which under unfavorable conditions is capable of inflicting a vast deal of damage and often irreparable injury, and even death. If the combined experience of those who have had much to do with syphilis could be given, a clinical picture of misery would be presented which would shock the medical and lay public into an earnest effort to control and check the spread of the disease. This is not an idle or rash statement of a syphilophobe, but is the calm opinion of one who for nearly forty years has been in almost daily contact with the disease in private and public practice, and is fairly well familiar with the literature of the subject.

I will not detain you with any detailed accounts even of the direful effects of the disease which I myself have observed and treated, as the scope of this paper is more general. But I must remind you how in neglected or unusually severe cases it may play havoc with any portion or organ of the body, even the most vital parts. You all know the very large share it plays in connection with locomotor ataxia, and the serious character of its brain lesions, as also those in the deeper structures of the eye, etc., and even the briefest mention of the many evil results which may come from the action of syphilitic poison would take much more time than can be now spared; the story of its relation to procreation, and hereditary syphilis, would alone occupy an evening. The truth therefore, is very plain, that syphilis is an important and serious disease, which should always engage most earnest attention, and that the physician should take great pains to instruct the patient, and, if necessary, even to frighten him, into giving proper and continuous care and treatment, sufficient to protect him against some of the more serious later inroads of the disease.

Another plain truth about syphilis is, that although it might be called a rebellious disease, as far as regards any natural tendency to recovery, it is yet very tractable if exactly the proper measures are carried out, in every respect, with perfect obedience and for a sufficient length of time.

When an intelligent patient first begins the treatment of a recently acquired syphilis, he generally expresses a perfect willingness to abide by every direction given, and promises to continue treatment faithfully, until such a time as the physician may direct its cessation; but, alas, how seldom is this actually the case! how few syphilitic patients are really discharged by the physician! and in how few instances can it be really said that the treatment has been perfectly carried out in every particular, for the fullest time which a wise and conscientious physician would desire!

It is a plain truth, therefore, that the laity, and I think also the medical profession, do not sufficiently realize the importance of a full and perfect treatment of syphilis, not only until the lesions present have entirely disappeared, but until sufficient time has elapsed, as recognized by those who know the disease best, for the elimination of the poison from the system. You all know that a full two years has been commonly considered the least time in which this can be accomplished by proper treatment; but some may not know that many of the best authorities are now regarding that as too short a period, and three, four, or even five years are judged necessary in some cases. Time does not permit us to go fully into this subject, but the profession should recognize that even as in the case of the spread of smallpox and other contagious diseases, the physician may be often responsible in a large measure for the spread of syphilis, if he does not adequately impress upon the patient the necessity of a full and proper treatment, as well as sanitary precautions, in such cases; for I am convinced that a good share of infection comes from imperfectly treated patients, who do not realize that until syphilis is entirely overcome they may communicate the disease through contagious lesions, mainly on the mucous surfaces, or may give the disease by heredity. Much of marital syphilis is thus acquired.

It has become pretty well established that alcohol is harmful to the syphilitic, indeed it has been shown that in a considerable proportion of the cases exhibiting late lesions of a serious character

these are due in a large measure to the baneful effects of alcohol on the tissues. This does not relate necessarily to very great overindulgence in alcoholic drinks, but occurs as well in those who have been moderate users even of wines, beer, etc.; the person affected with syphilis should, therefore, be a total abstainer, certainly during a period sufficiently long to have the poison thoroughly overcome by proper medical treatment.

Tobacco is not so actively harmful in syphilis, but the commonly accepted opinion that it had better be avoided is undoubtedly correct. In the early stages it pretty certainly increases the tendency to the development of contagious mucous patches about the mouth and lips, and in the later stages it increases the danger of cancerous degeneration in syphilitic lesions in the buccal cavity; by its effects upon the vasomotor nervous system tobacco may also act prejudicially in regard to some of the later effects of syphilis on the brain and nerve tissue.

Time does not permit us to dwell long on the subject of the treatment of syphilis, and, as in regard to so many other different diseases, there will probably always be more or less divergence of opinion in regard to many details of greater or less importance, in accordance with individual observation and judgment. But there are some facts, or plain truths, which it is well always to bear in mind. Mercury is still the one and only remedy which exercises a specific control over the disease. The forms and methods of its administration are very many, but it must be remembered that in each and every instance it is the mercury itself which does the good, the only question being as to the best method or combination whereby it may be made to permeate the system, with the least harm; so in many instances it is somewhat a matter of individual preference, based on experience, for one can generally, or at least often, do better work with a tool with which one is well acquainted than if one attempts to handle new ones continually, although recommended by ever so high an authority. My advice, therefore, is not to run after each novelty, but to adopt a good plan of treatment and stick to it, with such modifications as individual cases may demand. The dosage of mercury is a variable factor, and must vary with the case, and with the results obtained; the plain truth is that the individual must have sufficient of the remedy and for a sufficiently long time to overcome the poison.

The method of administration of mercury is a large subject which we cannot enter fully upon now; many modes have many advocates, and each has its advantages and disadvantages. The inunction method is relatively seldom used now in private practice, but in certain cases in hospitals and in infants, especially the latter, it is of very great value. Mercurial vapor, given in baths, is also rarely used, but at times serves a valuable purpose to effect rapid mercurialization. The administration of mercury by the mouth is, and probably always will be the common and favorite method of introducing the drug, and is that which I generally employ; but the plain truth is that, as ordinarily administered in general practise, it often fails in controlling the disease and its later effects as radically as could be desired. To be really effective it should be given to tolerance, the mouth being very carefully watched to avoid salivation; I constantly see patients with florid manifestations of syphilis who have been receiving only a quarter of a grain of protoiodide of mercury, three times daily, a totally inefficient dose.

The hypodermic administration of mercury is steadily gaining ground in the profession, and by many is advocated as the only proper method of treatment, in all stages of the disease; an opinion which I do not share, although I have had some little experience with it. It has its advantages and its disadvantages, which we have not now time to weigh, but the plain truth is that it is a valuable addition to our means of combating syphilis in many cases; we can certainly often produce very rapid effects thereby, and in instances where the brain or vital organs are involved this method of treatment has undoubtedly secured results which it would be very difficult to effect in any other manner. The details in regard to the preparations used, dosage, and technique of the operation have been so abundantly detailed in literature that I need not dwell on them here.

Iodide of potassium is constantly thought of in connection with the treatment of syphilis, but the plain truth is that of itself it has really no effect upon the syphilitic poison, although it is often erroneously given for this purpose; but as an adjuvant to mercury, in the removal of some of the later results of syphilis, it is of inestimable value; it also probably aids materially in effecting the rapid elimination of mercury from the system. All agree, therefore, that early in the disease it is of relatively little service, while late in the disease its value is incontestable. But many err in employing it then alone, whereas the plain truth is that more or less mercury is needed as long as there are any manifestations of the disease, indeed until the full time has elapsed, which experience has shown to be necessary to overcome the poison. The enormous doses of iodide of potassium which are sometimes given are commonly both useless and irrational, although, of course, in certain cases large amounts may be necessary to cause the absorption of effused products. But it is a plain truth that even in these cases much less of the iodide will be needed if mercury is used judiciously in addition, even in the latest stages of syphilis.

Another plain truth, which seems to be too often forgotten in practice, is that the patient is constantly to be regarded and treated, quite as much as the disease itself. Too many seem to regard only the infection, and from first to last administer mercury and iodide of potassium quite regardless of the patient's condition, and to the utter disregard of the diet and mode of life or the manner in which the bodily functions are performed. It must always be borne in mind that we have to do with a living animal organism, of marvelous complexity, into which a foreign poison has entered, and in which it multiplies, modifying materially the actions and functions of the component parts: and while administering the antidote to the poison one must continually bear in mind the many other elements which may tend to derange the health of the individual. For all recognize that the syphilitic virus acts very differently in different persons, and under various circumstances: the sad cases of malignant and galloping syphilis which one sometimes sees, have not so much to do with a greater quantity or virulence of the poison as with a depraved state of health and many errors of the system, which it is the duty of the physician to correct.

Finally a few words must be said in regard to

the plain truth concerning the supposed value of mineral springs in connection with syphilis. This matter has been repeatedly discussed in our dermatological circles, and I am confident that I speak the views of others who also know, when I say that their value and importance has been very greatly overestimated, both by the laity and by the profession at large. Indeed I would go further and say that much harm is often done by the false security which patients often have who have undergone what is often called a "cure" at one of these places; we all know that syphilis cannot be cured by any brief course of treatment, however severe; and yet, having had such a "cure," patients will often entirely neglect treatment until the disease insidiously attacks vital organs, often to such a degree that subsequent remedial measures cannot repair the damage done. True it is that many patients with syphilis do undergo these so-called "cures" with distinct benefit; but when the matter is carefully investigated it will be found that they have been submitted to very active and often heroic treatment with mercury and iodide of potassium at the springs, and to this the gain is entirely due; although it must be admitted that the change of air and scene, together with the natural hope and expectation of benefit, have contributed in some measure to the result. It would perhaps surprise you to know how very, very seldom those who understand syphilis best, ever advise a trip to one of the springs. I have seen very many syphilitics who have made the trip, often at great pecuniary sacrifice, who have subsequently acknowledged the mistake made, and I do not recall a single instance where I have regarded it necessary or wise for the patient to undertake this method of "cure" at any great personal sacrifice.

In closing this rather rambling talk upon some plain truths about syphilis I have to apologize for the brief and imperfect manner in which each point has been considered, as only a limited time was assigned me; for there are a number of them which could each be elaborated into a full paper. But in the spirit which I mentioned at the beginning, I have only tried to humbly fulfil the request of your honored president, and to put before you in a simple manner some of the plain truths and practical points concerning syphilis which are of value to keep in mind, and which form the basis of my daily experience with the disease.

531 Madison Avenue

THE DIFFERENTIATION OF BLACK PIGMENT FOUND IN THE LIVER, SPLEEN, AND KIDNEYS FROM COAL DUST OR OTHER FOREIGN DEPOSITS.

By FREDERICK GAERTNER, A.M., M.D., LL.D.,

PITTSBURG, PA.

Pathologists all over the world have long been interested in pigmentations in the interstitial tissues of the various organs, and particularly the abdominal organs. This is of either an organic or inorganic character. The pigmentation to which I first, in 1882, called attention is the black pigment of soot and coal dust. I have had occasion to make and help to make some twenty-five hundred autopsies, with the view of determining (1) what this black pigment is which frequently is found deposited in the liver, spleen, and kidneys; and (2) its origin and causes.

During the years 1883 to 1885, both inclusive, I was appointed expert microscopist by my esteemed friend and teacher, Prof. von Recklinghausen of Strassburg, to make a thorough scientific investigation into this subject, in order to determine its

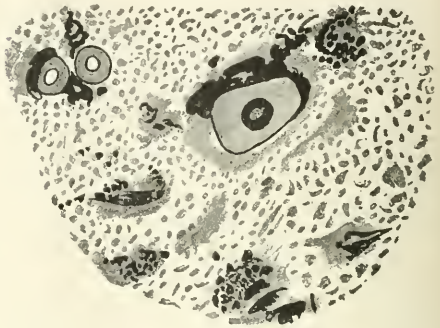

Fig. 1.—Microscopical section of the spleen with coal-dust deposits, anthracotic metastasis.

pathological character, its causes, and etiology; then to write a dissertation upon this subject. This, the title of which was: "Concerning the Black Pigment Found in the Liver, Spleen, and Kidneys," was originally published in 1885.

I have since then made some additional important discoveries concerning the differentiation and identification of the pigments frequently found deposited in the liver, spleen, and kidneys from soot and coal dust or other deposits, such as small minute particles of stone, sand, bone, slate, glass, wood, iron, and steel dust. These researches were made with the view to determine absolutely whether it is possible that these inhaled substances can eventually be found deposited in these abdominal organs, and how.

Dust is one of the great disseminators of diseases by carrying and depositing specific microorganisms in the lung tissue, there to develop, multiply, and by absorption produce infectious diseases. The effects of dust on the human being depend upon the following factors: (1) The kind of dust; (2) the

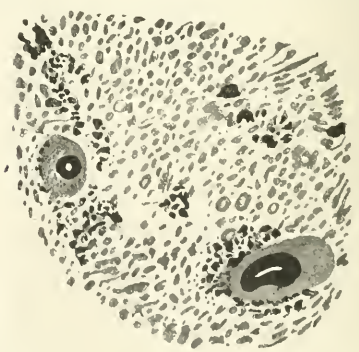

Fig. 2.—Microscopical section of the spleen with soot deposits.

amount of dust; (3) the constancy of its presence; (4) the susceptibility of the individual; (5) the promptness of its absorption by the lymphatics and the deposition in the lymphatic gland; (6) the chemical action or reaction on these tissues and

to what extent they are soluble in the secretions; and (7) the amount of irritation, *i.e.* inflammatory condition they may produce.

The composition of dust varies according to the locality and local conditions. For instance, in a city where much coal is burned the atmosphere is constantly loaded with small carbon particles; in

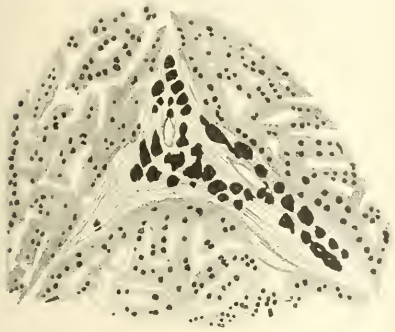

Fig. 3.—Microscopical section of the liver with coal-dust deposits.

stone works the dust consists almost entirely of fine particles of stone, generally very hard and with sharp edges; in factories, where metal is ground, we find a metallic dust, also with sharp edges.

It has been known for years that workers in stone and metal grinders suffer more frequently from bronchial and lung diseases than do individuals in other trades, and oftentimes such cases have been mistakenly regarded as tuberculous, when in fact they are mechanical inflammatory conditions. Coal miners suffer more from these diseases than do other miners, as the coal is very readily reduced to a fine powder with sharp edges. The deposit of coal dust in the lungs and bronchial lymph nodes (see Fig. 6) may be very great in amount, causing these organs to appear black, enlarged, and very tough and gritty on section.

The term given to deposits of dust in the lungs is pneumonoconiosis. This is the general name for such deposits, but I have given special names to the various kinds of dust. For instance, the de-

Fig. 4.—Microscopical section of the liver with coal-dust and soot deposits.

posit of coal dust in the lungs is called anthracosis; of metallic dust, siderosis; of stone dust, chalicosis; of clay, aluminosis; of bone, ossiocosis; of sand, silicosis; of wood sawdust, lignicosis; glass, vitricosis.

The inhaled dust particles are of two distinct classes, inorganic and organic.

In the first class, beside those above mentioned, are included the various salts which, when dissolved in the secretions, cause a chemical irritation. A good example of this type is the dust of the alkali deserts of our western states.

Fig. 5.—Microscopical section of the kidney with coal-dust deposits within an atrophied glomerulus.

To the second class belong the pollen of various plants, which, in peculiarly susceptible individuals, causes an intense inflammation known as hay fever, rose cold, etc. Then come the different microorganisms, and here I must mention first of all the tubercle bacilli (Fig. 7), besides many other pathogenic microorganisms, such as the streptococcus, staphylococcus, micrococcus, pneumococcus, Klebs-Loeffler bacillus, even that of typhoid fever, anthrax, and bubonic plague.

A dust-laden atmosphere may therefore contain many or different kinds of dust, and one or more different varieties of pathogenic microorganisms; they all have to travel one channel; that is, by the lungs, there to be deposited, eventually absorbed by the lymphatic vessels and capillaries, and ultimately deposited in the lymph glands at the hilus of the lungs, and then through certain inflammatory pathological changes at the hilus, finally, by perforation, carried by the blood-vessels and deposited in the abdominal organs.

It practically makes no difference what kind of dust one may have inhaled, it is driven to the lungs directly into the alveoli and here is the place where the first damage is done; the smaller dust particles are absorbed, as mentioned above, whereas the larger particles cut their way into the lung tissue, producing oftentimes hemorrhages and chronic

Fig. 6.—Coal-dust deposit in a lymph node.

bronchitis and pneumonia, and eventually become encapsulated.

No subject in pathology or pathological anatomy has caused more worry and confusion than the pigmentation of the abdominal organs, and many anato-

mists and pathologists have been engaged during the past century, and particularly during the last three decades, in trying to solve the problem, how the black pigmentation, which so frequently is observed in the liver, spleen, and kidneys, originates; if it can be looked upon as a transportation of some foreign substance, such as coal dust, etc., from

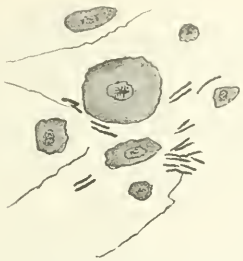

Fig. 7.—Tubercle bacilli in sputum.

other localities, or simply as an expression of some dyscrasia, especially the malarial dyscrasia.

In the first decennary of the past century this melanosed condition was considered quite normal, but since, in 1847, by means of the microscope, pigment was found in the spleen, and at the same time it was also discovered in the blood of the cadaver, the belief arose that it might have been brought about by intermittent fever, and the discoloration observed in melanemia was then denominated "melanotic pigmentation." Many authors, especially the French, were of the opinion that this black pigment was derived from the blood as the result of the destruction of the red blood corpuscles, the coloring matter of the blood (hemoglobin) being transformed into this black pigment.

These views were accepted until it was proven by chemical analysis and tests that this black lung pigment was identical with coal dust and soot. In 1878 Soyka narrated a case in the *Prager medizinische Wochenschrift* in which this black pigment in the spleen, liver, and kidneys was found to be identical with coal pigment; this being the first case cited in literature of which we have any knowledge.

Soyka's case was that of a man, seventy years old, afflicted with a high grade of pneumonoconiosis, in which he also found coal pigment in the liver, spleen, and kidneys. Soyka, however, believed that this coal dust passed through the bronchial lymphatic glands, then through the thoracic duct, and from there was carried into the blood and deposited in the above named organs. This hypothesis Weigert was right in disputing, with the remark that if the lymphatic glands were not continent every adult would have such deposits in different organs, which is positively not the case; every adult, however, possesses more or less anthracotic bronchial lymphatic glands; this black pigmentation is certainly not an expression of malarial dyscrasia, since in Germany the malarial forms from which melanemia is produced rarely ever occur, although a deposit of black matter in the liver and spleen is by no means infrequent, as Weigert and Roth have recently affirmed.

The latter author also expressed his views in a lecture published in the *Correspondenz-Blatt für Schweizer Aerzte*, Jahrgang XIV, 1884, to the effect that this pigment is probably carried by the blood, and he is of the opinion that this might be looked upon as a coal dust metastasis. Weigert expresses the same opinion in the *Fortschritte der Medicin*, No. 14, 1883, in which he asserts that the diffusion of coal dust and soot occurs through the blood-vessels, and states that in Leipzig, the home of the observer, severe malarial cases never occur, and that therefore for this reason alone and also because the spleens examined are oftentimes completely atrophied, the origin of melanemia (melanosis) should be excluded.

I have recently again demonstrated beyond a doubt through scientific examinations, and from chemical, microscopical, and bacteriological tests, and by comparison have proved absolutely that this black pigment, which frequently is observed in the abdominal organs, presents no material difference from inhaled coal dust and soot frequently found in normal lungs, especially in those of coal miners and chimney sweepers, etc. Concerning this black lung pigment, Knauff says, in Virchow's *Archiv*, Vol. No. 39, page 458: "I have never seen the lungs of adults that did not show a black pigmentation. The lungs of newly born infants, however, never contain black pigment; those of old people, as a rule, a large quantity."

It is well known that the English first expressed the idea that this black pigment which so plentifully exists in the lungs of coal miners and chimney sweeps is due to the inhalation of coal dust and soot. Pearson was the first (see Philosophical Transactions, 1813, page 159), after him Lecann and Melsens, to explain the chemical character of this black pigment contained in the lungs and bronchial lymphatic glands. They showed that the black mass examined burned without flame and without leaving any ash behind; furthermore, that it was insoluble in nitric, hydrochloric, and sulphuric acids or in caustic, potash, or soda, etc., and that it was only acted upon when placed in boiling water through which a current of chlorine gas was passed. It was therefore identical with coal and soot. Then by further chemical analysis it was found to consist of 96 61/100 per cent. of carbon and 83/100 per cent. of hydrogen; therefore nearly pure carbon. It was consequently no organic pigment.

Later, Pearson and Laennec expressed their views concerning the so-called physiological anthracotic lung pigment; however, Gregory, Marchall, Thomson, Rilliet, and others, during the early part of the past century, acknowledged the possibility of the introduction of coal dust, particularly soot, into

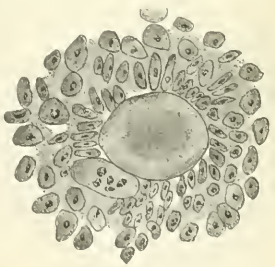

Fig. 8.—Miliary tubercle.

the lung tissue and the production of an exquisite pathological anthracotic lung, as seen in coal miners.

But it is only since Traube's accurate microscopical examination that it has become generally accepted that the discoloration of the lung is due

to the presence of coal dust within the air passages and alveoli.

Following this it was tried, and with success, to solve the problem by experiments, and it is my duty here to mention, above all others, the names of Knauff, von Ins, and Ruppert.

Knauff asserts (Virchow's *Archiv*, Vol. XXXIX, page 442, 1867) that in animals confined in the smoke chamber for a time, the inhaled coal dust penetrated to the extreme portions of the breathing organs; further, that the pigment for the most part adhered to the cellular elements, but free pigment also lodged in the alveoli. These cellular elements were partly free, partly more or less fixed to the walls. The filling of the cells with coal dust was, as a rule, incomplete. The same formations were also found lodged in the parenchyma beneath the surface of the alveoli. A narrow but distinctly visible strip of colorless lung tissue separated the lumen of the alveoli from the stratum containing the coal dust. The black particles either lay scattered and seemingly without definite order, or formed more or less connected lines. The arrangement of coal particles in ramifying lines appeared still more distinctly on the surface of the lungs. From these manifold branching lines connecting chains proceeded, so that the whole presented the appearance of a vascular system. And thus the design of the injected lymphatic vessels was traced by the coal dust. When an animal had been exposed to an atmosphere thickened with coal dust or soot, and the roots of the lungs were more closely examined immediately after death, the lymphatic canals appeared as gray lines, just as if India ink had been artificially injected. The liquid contents of the canals could be moved hither and thither by stroking and pressing, more easily, of course, towards the lymphatic glands than in the opposite direction because of the opposition offered by the imperfect valvular apparatus. On closer examination the gray contents were found to consist of fine granules of coal, partly free, partly enclosed in the cells, of exactly the same appearance as that in the lung parenchyma. From the above experiments the following was deduced: From the surface of the alveoli the coal dust and soot force their way into the parenchyma of the lung: there it must be supposed free communications exist, although the passages cannot be demonstrated. But that these passages may be traced was later shown by me ("Experimental Histological Research"), and I demonstrated that between the flattened, transparent epithelial cells lining the alveoli are minute openings, "stomata," leading from the cavity of the air cells into the lymph-lacunæ of the alveoli wall. These stomata are more distinct during expansion, *i.e.* inspiration, than in the collapsed state. Inspiration by its expanding the lungs, and consequently also the lymphatics, greatly favors absorption. Through these stomata, and also through the interstitial cement substance of the lining epithelium, may penetrate particles, such as soot from a smoky atmosphere, pigment artificially inhaled, even minute particles of iron, steel, glass, bone, stone, wood, or sawdust, then cellular elements, such as mucus or pus corpuscles, and germs that have been carried into the alveoli from the bronchi by natural inspiration. Then they pass into the lymphatic vascular system, close to its finest roots (the lymph-canaliculi of Recklinghausen) which, of course, are very difficult to demonstrate. From here they pass into the lymphatic vascular capillaries, and are gathered particularly where several lung alveoli meet, chiefly at the point of transmission of the infundibula into the alveolar passages. Just here the dust particles accumulate. The lymphatic vascular system mingles and intercommunicates in the subpleural, but especially in the peribronchial and perivascular tissues; and through these channels the dust particles move and are carried into the bronchial and tracheal lymphatic glands, and there deposited.

As Slavjansky proved (Virchow's *Archiv*, Vol. XLVIII, page 326) that lymphoid cells appeared in the lung alveoli after experimental inhalations of dust, in which especially cinnobar, ultramarine, indigo, and coal dust were used, or in animals compelled to remain for a considerable time in a dust-laden atmosphere. These lymphoid cells, together with the lung epithelia and particles of mucus were laden with the inhaled dust; moreover, free dust was found in the lumen of the alveoli as well as in that of the bronchiæ. On the other hand, the cylindrical epithelial cells of the bronchia were entirely free from dust. Further, Slavjansky pointed out that in rabbits that were subjected to artificial inhalation of cinnobar within three days cells containing this coloring material were found in the cortical layers of the lymphatic glands situated at the base of the lung. From all these researches it has been concluded that the dust, cinnobar, coal dust, etc., inhaled under artificial or natural conditions are driven into the distant extremities of the breathing canals, there received by the cellular elements, lymphoid, and mucus cells, perhaps also by the flat and transparent epithelial cells lining the alveoli, and these cells are then either absorbed by the lymph-canaliculi, or are conveyed into the lymphatic vessels. From the small lymph-canaliculi they are led into the lymphatic vessels and thence into the lymphatic glands situated at the base of the lungs and deposited.

Concerning the consequences of this deposition in the lymphatic glands, I wrote in the *Correspondenzblatt für Schweizer Aerzte*, Jahrgang XVI, 1886, as follows: "The changes vary according to the degree of discoloration of the lymphatic gland; if it is but trifling, it may be endured without further disturbances, but if considerable then local inflammation, lymphadenitis and perilymphadenitis may set in. In consequence of the latter, on the one hand, a development of cicatricial tissue, a common slaty induration of the tracheal and bronchial lymphatic glands; and, further, a shriveling and a destruction of the lymphatic structure may result; on the other hand, the process may become acute, and soon abscesses of the lympatic glands, with suppuration of the capsule and the neighboring tissue, may follow. The process may also spread to the neighboring organs, such as the bronchia, veins, arteries, heart, or pericardium, which may lead to fatal results; or the former indurated mass may soften, slough, and become a slaty pulp, which microscopically and chemically presents nothing else than anthracotic pigment in a free state or deposited in lymphoid cells; also cells of fatty degeneration, cholesterine, clots of necrotic tissue, at times also leucin and tyrosin, occasionally even lime. To this disintegrated united product I gave the name in 1885 of 'slaty cheese substance.'"

Should the process take on a chronic course, it is not seldom found in dissecting that the more or less enlarged, slaty, indurated lymphatic glands, on being cut into, present a striped appearance, obviously a product of the chronic inflammation of the gland tissue. The most varied local changes result from prolonged local inflammation of the lymphatic

glands. In regard to this Weigert has already declared that very soon inflammatory adhesions with the bronchia at the base (hilus), *i.e.* with arteries, veins, nerves, and lymphatic vessels will occur, and at times also with the vena cava inferior and superior, and occasionally even with the vena azygos dextra.

In 1885 I said that if the inflammatory process remains confined to the lymphatic gland and its capsule, calcification may result; even the entire gland, together with the capsule, becoming calcified *in toto*. These calcified masses may be conveyed by means of perforation into the air passages and out of these to the exterior; or they may cause an obstruction of the air passages and so directly lead to death by suffocation, or indirectly by secondary bronchopneumonia and hemorrhages. In regard to this there occur in the literature on the subject a few interesting cases: An observation of Edwards was described in the "Medico-chirurgical Transactions," 1854, Vol. 37, p. 151; a second case was published by Roth, *Correspondenzblatt für Schweizer Aerzte*, Jahrgang XIV, 1884; the third case was dissected and demonstrated by me, in 1884, in the presence of my highly esteemed teacher, Prof. Dr. von Recklinghausen. In this instance it appeared that the entire gland, together with its capsule, was calcified *in toto*, and this mass had penetrated the left principal bronchus, to the walls of which it was somewhat firmly adherent. Chemical analysis showed that this mass consisted, to a large degree, of carbonate of lime, gelatin-producing substance, and a trace of sulphuric acid.

The local changes resulting from the anthracotic indurations of the lymphatic glands are frequent, oftentimes complicated and manifold. They have been most elaborately described by Zenker (Handbuch der Pathologie, VII, 1, 2, Auflage, 1871, Anhang, page 66), and by Eternot (Recherches sur les affections chroniques des ganglions trachéo-bronchiques et les suites de ces affections, Geneva, 1879), and by Oekonomides (Dissertation über die chronische Bronchial-Lymphdrüsen Affection und ihre Folgen, Basel, 1882). From all these communications the following is deduced (Gaertner, 1885): If the chronic inflammatory process, adenitis, and periadenitis continue, it will not remain long confined to adhesions with the neighboring organs, such as the bronchia, arteries, veins, lymphatic vessels, and blood-vessels, even with the esophagus and the trachea, etc., but may, on the one hand, result in dilatation of these organs by retraction, or, on the other hand, in a contraction by compression. Furthermore, that the walls of the pulmonary vessels or bronchi may not only become necrosed and break down, but finally become perforated. At the site where this chronic slaty indurated lymphatic gland lies in contact with a blood-vessel or bronchus, the anthracotic pigment or any other foreign substances may directly enter the blood stream or the breathing passages, or such masses may be conveyed into and carried through the blood by means of the bronchial vessels (arteries and veins) which run along the bronchi and supply them with blood. This was demonstrated beyond a doubt by me in 1882, in 1885, and now again.

Here consequently lies the real etiological moment for the transportation of anthracotic pigment—coal dust, soot, or other minute substances, such as iron or steel, wood, bone, glass, sand, paint dust, even germs, etc.—into the various organs, especially the liver, spleen, and kidneys; also into the peripor-tal and mesenteric lymphatic glands, even into the marrow of the bone, by means of the blood-vessels. To this pathological process, if it contains soot or coal dust, I have given the name, in 1885, "coal dust, or anthracotic metastasis."

The occurrence of this coal dust metastasis in the liver and spleen is, according to the most recent investigation, by no means infrequent; eleven cases of this kind were investigated in one month by Roth. I had the opportunity, under the guidance of Prof. von Recklinghausen, from 1883 to 1885, of examining carefully 275 typical cases of this kind. These original researches were made and especially directed to the answering of two questions: (1) Whether the pigment deposited in the abdominal organs corresponded microscopically and chemically with that of the enlarged and for the most part slaty indurated bronchial and tracheal lymphatic glands; and (2) whether the pigment was always present in the abdominal organs, when such a gland had perforated the walls of a blood-vessel or bronchus.

If the abdominal organs contain anthracotic pigment it is by no means necessary that they should be changed; they may be normal in size, or they may be enlarged or atrophied, although the two latter changes are not the result of the deposit of coal pigment or any other foreign substances, since coal pigment produces no irritation whatever in the structure of these organs. The pigment is for the most part taken up by the cells and especially by the leucocytes. Within these organs it only occasionally leaves the cells and settles in them permanently (see Figs. 1 to 5).

Soot and coal dust deposition within the liver, spleen, and kidneys, or in any other organs or tissues (which I have called "anthracotic metastasis"), is now recognized by nearly all pathologists and anatomists as a distinct abnormal, *i.e.* altered physiological, condition, and is mentioned in nearly all the latest scientific works on pathology and pathological anatomy as a distinct pathological condition. I have given in detail and fully described what changes it must undergo and through what channels it must travel to be conveyed and deposited in these distant abdominal organs in order to form this secondary anthracotic metastasis.

Consequently coal dust and soot deposits within these organs as a rule do not do any great harm or damage, but all the damage is done at the base of the lung, just here at this very point where lymphadenitis or perilymphadenitis is set up or rather brought about by the absorption, infection, and constant irritation of this coal dust, or other foreign substances taken up into the lymphatic glands and its surroundings; eventually there occurs a perforation into an artery or vein, whereby the material is taken up by the blood-vessels and carried over the entire body and deposited at certain anatomical points, thus producing this secondary metastasis. But immediately surrounding these small perforations is the very place where all the serious damage is done, and this is as a rule the direct cause of death.

I will add that nearly every adult has more or less enlargement and induration of the lymphatic glands at the base of the lung, which is either of anthracotic or produced by dust particles loading the atmosphere breather by these individuals. This pathological condition should be called in accordance with whatever foreign substance it may have been absorbed and retained to produce it; then the same nomenclature should be applied to such deposits in the abdominal organs.

The Spleen.—In the spleen it lies principally along

the smaller arteries (perivascular) and in the marginal zone of the malpighian bodies, and it is also found in the perivascular lymphatic canaliculi and in the lymphatic vessels of the capsule. (See Figs. 1 and 2.) It is for the most part confined to cells, especially leucocytes, round cells, and the spindle-shaped and star-shaped cells. It presents a finely granular black pigment which is not affected by caustic soda or potash, caustic ammonia, muriatic, nitromuriatic, or sulphuric acids, or ferrocyanide of potassium. It is not affected by the various coloring materials which are used in staining the tissues. The coloring fluids which I have used especially are: carmine, Ranvier's picre-carmine, alum-carmine, Orth's lithion-carmine, borax-carmine, hematoxylin, and the various aniline colors, such as gentian-violet, methylene-violet, methylene-blue, fuchsin, and several others. This black spleen pigment corresponds exactly, as well microscopically as chemically, with the coal dust of the lungs and of the bronchial and tracheal lymphatic glands.

The Liver.—It is very rarely visible macroscopically in the liver. If it is present it assumes, as is well known and as Weigert has pointed out, a light gray color. Microscopically it is seen deposited especially in the periportal interacinous tissues along the smaller arteries and at times also within the cells of the tissue along the vena centralis, also in the lymphatic vessels of the capsule and in the periportal (interlobular) lymphatic ducts. (See Figs. 3 and 4.) It has never yet been possible for me to demonstrate a deposit of coal dust within Kupfer's star cells of the liver.

The Kidneys.—The deposit of anthracotic pigment in the kidneys is by no means a frequent occurrence, although it may exist abundantly in the liver and spleen. I was able, however, in several cases to discover it deposited, although scantily, within an atrophied glomerulus (Fig. 7). I think I am able to explain this anomaly by the fact that the kidneys are not only very abundantly supplied with blood, but that the blood in them changes rapidly, by rapid circulation. In the periportal and mesenteric lymphatic glands the anthracotic pigment is led by way of the perivascular lymphatic ducts, which fact may be determined because the capsule of the lymphatic glands and the peripheric lymphatic ducts are found laden with it. This black, finely granular pigment is not easily to be confused with bile pigment (bilirubin); it might more easily be confused with iron pigment, micrococci, fatty degeneration of the epithelium cells, with the so-called cells of fat particles (Gluge's corpuscles), or finally with the putrid products of the epithelium.

The iron pigment as it is found in pernicious anemia, I have demonstrated by ammonium sulphate, or, still better, by ferrocyanide of potassium and diluted muriatic acid.

The latter is preferable, since by its use the microscopic sections have a very intense shade of dark-greenish blue microscopically; and it may be seen even macroscopically; that is, the iron pigment is colored distinctly green or light blue. In order to produce lasting and beautiful microscopic specimens the following is the best method: Allow the sections to lie from eight to ten minutes in Ranvier's picro-carmine, then wash them well in distilled water; next place them for five or ten minutes in ferrocyanide of potassium, then for a few minutes in diluted muriatic acid; wash again; dehydrate in absolute alcohol, clear in origanum or bergamot oil, and embed in xylol. Canada balsam, or damar lac. If the cuttings are placed in glycerin the iron pigment very quickly (within three weeks) loses its blue-green shade, and it is then no longer possible to recognize iron pigment as such until the sections have again been successfully treated with ferrocyanide of potassium and with diluted muriatic acid.

The differential diagnosis between coal dust (anthracotic metastases, Gaertner) and micrococci is by no means easy. Both are finely granular and brownish black in color, both resist the various reagents, acids and alkalies; both lie for the most part within the smaller arteries. The difference exists, on the one hand, in that the anthracotic pigment lies principally within the cells, which is very unusual for the micrococci; and on the other hand—and this is the principal difference—in its relation to the different staining fluids, especially aniline dyes, and also to reflected and direct light. To distinguish anthracotic pigment from fatty degenerated epithelial cells, fatty particles, etc., it is sufficient to note that the anthracotic pigment is not affected by the agents that are used for recognizing fatty degenerations, such as with osmic acid, sulphuric ether, etc.

Finally, concentrated mineral acids serve to distinguish the anthracotic pigment from the putrid products of the epithelial cells, which, especially after treatment with acetic acid, under the microscope appear to be entirely black. In mineral acids the epithelium cells immediately dissolve, while the pigment, as before stated, remains unchanged.

It appears from my original pathological investigations, made during 1883 to 1885, and since then new researches and observations made upon the human subject by clinical and chemical tests and observations, from examinations upon the cadaver, and from experimental tests on rabbits, cats, and dogs with artificial and forced inhalations of cinnobar or other dust-laden atmosphere, that the intensity of the black pigmentation in the abdominal organs increased in exact proportion to the quantity of coal-dust and soot deposits in the bronchial lymphatic glands; so that it increases according to the amount of such deposits in the glands, and as the walls of the neighboring blood-vessels are penetrated and infiltrated at the point of perforation with this anthracotic substance from these enlarged indurated bronchial and tracheal lymphatic glands.

Since the cases of my investigation in this respect are of great importance and support the theory that the black pigmentation of the abdominal organs is anthracotic and not melanotic, I give here very briefly the results of my investigation of ten of the most typical cases examined.

Case I.—Hemorrhagic pleuritis, thrombosis of the pulmonary artery and gangrene of the surrounding tissues. The lungs are strongly affected with anthracotic pigmentation, the normal capacity as to the quantity of blood and air in them being diminished. The right lung is affected with senile atrophy and shows some vesicular emphysema; circumscribed slaty indurations are not apparent; on the contrary the lower lobe of the left lung is compressed to a great extent by a hemorrhagic exudation. The tracheal and bronchial lymphatic glands at the hilus are large and slaty, a few of them being of very solid consistence. Some of the same are adherent to the bronchi and blood-vessels near which they lie. A shrunken black lymph gland lies close to the right principal bronchus and is adherent to it. An incision being made, a small opening is found, leading into the interior of the gland. A second enlarged, slaty, indurated lymphatic gland lies close to the principal branch of the pulmonary artery and is firmly adherent to it. The lumen of

the artery is narrowed at that point where the solid black gland lies, and the wall itself is considerably pigmented and infiltrated by this anthracotic pigment. On opening the artery an autochthonal thrombus is found, which obviously came into existence through the contraction and the defect in the endothelium. The thrombus gave rise to the surrounding gangrene. A deposit of anthracotic pigment is found in the liver and spleen. (See Figs. 1, 2, and 3.)

Case II.—Cancer of the gall-bladder, with regional metastases in the liver and mesenteric lymphatic glands. Both lungs are strongly affected with anthracotic pigmentation; no particular indurations are present. The right lung shows croupous pneumonia, to which the patient succumbed. The left lung is, on the contrary, abundantly supplied with blood, but its capacity for air is greatly increased. The bronchial lymphatic glands at the base are very large, indurated, and slaty. One of them is extremely black and shrunken; it lies close to the principal branch of the vena pulmonalis, and is firmly adherent to it, the result of adenitis and periadenitis. The wall of the vein is completely penetrated by this black anthracotic pigment, which chemically and microscopically corresponds absolutely with the inhaled coal-dust of the lungs and that in the tracheal and lymphatic glands. An incision into the vein shows a small opening leading into the interior of the black lymphatic gland. In the spleen and liver is found a large deposit of pigment, especially of two kinds—brown and black. Macroscopically only brown pigment can be seen, which, under the microscope, was found to be strongly ferruginous (consisting chemically of hydrated sesquioxide of iron. Microscopically the black anthracotic pigment could be easily seen, deposited along the smaller arteries (perivascular), and in the outer zone of the malpighian bodies. (See Figs. 1 and 2.) In the liver the black pigment was deposited not only within Glisson's capsule, but also in the tissue cells along the vena centralis. (Figs. 3 and 4.) There was no anthracotic pigment in the kidneys; merely iron pigment.

Case III.—Embolism of the pulmonary arteries and a simultaneous slaty and brown induration of the lungs. Anthracotic pigmentation of the lungs is decidedly marked; the capacity of both lungs for blood is greater than normal, but that for air less. The edges of both lungs are slaty; the lower lobes, on the contrary, are indurated and quite brown. Infarctions or softenings are not apparent. The bronchi are somewhat dilated, but there are no cavities. The tracheal and bronchial lymphatic glands at the hilus are enlarged, solid, and slaty, a few of them being quite adherent to the neighboring bronchi and pulmonary arteries, the walls of which are more less infiltrated with coal pigment. An incision into the right principal bronchus shows a radiating cicatrix, in whose center there is a small opening which communicates with the existing cavity in the interior of this black gland. A second lymphatic gland lying close to the left principal bronchus is calcified *in toto* together with its capsule, and this mass has perforated the walls of the bronchus, but still clings rather closely to it. This is the case studied by me under Recklinghausen. The liver and spleen showed a condition of cyanotic atrophy, and a deposit of anthracotic pigment.

Case IV.—Exquisite slaty induration of both lungs (chalicosis). Anthracotic pigmentation is marked; both lungs are highly marbled with slaty indurated cicatrices; the capacity for blood is rather increased, but that for air is diminished; the formation of cavities, or softening, is not present. The tracheal and bronchial lymphatic glands at the base are very large, indurated and slaty; one of them is shrunken, entirely black, and lies close to the principal branch of the vena pulmonalis, and is adherent to it. At the point of junction the wall is considerably infiltrated with anthracotic pigment and slaty substances. An incision into the vena pulmonalis discloses at the place of the junction with this shrunken, slaty, black gland, a diverticulum, producing a traction-varix, evidently the product of chronic inflammation (lymphadenitis and perilymphadenitis chronica), with simultaneous shrinking of the glands. In the liver and spleen there is a deposit of anthracotic pigment and a chalicosis metastasis.

Case V.—Acute miliary tuberculosis of the lungs in a case of stonecutter by trade; pneumonia chalicosis chronica (Fig. 8). Anthracotic pigmentation of both lungs is only moderate, but highly marbled with fine tubercles of minute stone particles, to which I have given the name of "miliary stonecutter's tubercle." Slight, slaty induration, with marginal emphysema; no formation of cavities or infarctions. The bronchial and tracheal lymphatic glands at the base are enlarged, indurated, and slaty; some are adherent to the bronchi and the surrounding vessels, the walls of which are more or less infiltrated with anthracotic pigment and minute stone particles. On opening the bronchi and blood-vessels there is found a communication with the left principal bronchus. In the liver and spleen is found a deposit of black pigment; also very minute particles of stone—a "chalicosis metastasis."

Case VI.—Exquisite slaty induration of the lungs. The anthracotic pigmentation of the lungs is decidedly marked; the upper lobes of the right lung are almost devoid of air, and are considerably indurated with slaty cicatrices, in consequence of which bronchial cavities (bronchiectasis) have been formed. The quantity of blood in these lobes is diminished. On the contrary, the right lower lobe and the entire left lung have an increased capacity for blood, but are affected by vesicular emphysema. The bronchial lymphatic glands at the base are enlarged, indurated, and slaty; a few of them are to a great extent adherent to the neighboring bronchi and pulmonary arteries, the walls of which are somewhat infiltrated with coal pigment. A larger, black, lymphatic gland is somewhat softer than the others and adherent to the right principal bronchus, the wall of which at the place of juncture is greatly infiltrated with anthracotic pigment. An incision into the bronchus shows a steel-like, slaty cicatrix, in the center of which is disclosed an opening. In the liver and spleen there is a deposit of black pigment.

Case VII.—Edema of the lungs. Anthracotic pigmentation of both lungs is strong, but there are no special indurations; blood capacity is markedly increased; there is cyanotic congestion, and the capacity for air is diminished. The bronchial and tracheal lymphatic glands at the base are very large and black, but not especially indurated; a few of them have grown fast to the surrounding vessels, the walls of which are streaked with coal pigment. A large black gland lies close to the right principal bronchus and is adherent to it. An incision discloses a breach in the principal bronchus. The spleen is very large and fibroid in character (chronic splenitis fibrosa). Macroscopically the coal pigment is visible and is grouped principally along the arteries and in the periphery of the malpighian bodies, and lies

in the lymphatic vessels of the capsule as a black, finely granular pigment. In the liver the pigment is macroscopically not visible, but only microscopically; it is found especially along the smaller perivascular arteries, in the interlobular tissue, in the cells of the tissue along the vena centralis; also even in the larger perivascular lymphatic spaces and in the lymphatic vessels of the capsule. (See Figs. 3 and 4.) In the kidneys no pigment could be found.

Case VIII.—"Stonecutter's lung" (chalicosis pulmonum). Anthracotic pigmentation is marked, and the lungs are extensively dotted with little specks of almost stony hardness (miliary stonecutter's tubercles, Gaertner), but show no especial slaty induration; the blood capacity is increased and that of air diminished. Infarction or the formation of cavities is not present. The bronchial and tracheal lymphatic glands at the base are enlarged, indurated, and slaty; several of them are adherent to the bronchi and vessels, the walls of which are more or less infiltrated with coal pigment. A shrunken black gland is adherent to the right principal bronchus. The right bronchus being opened at the point of junction, a radiating, slaty cicatrix is disclosed, the center of which is disintegrated (necrosed) so that with a probe one can easily penetrate into the interior of the gland. Black pigment is deposited in the liver and spleen, with a decided chalicosis metastasis.

Case IX.—Slaty induration of the lungs. Exquisite anthracotic pigmentation of both lungs is quite marked; they appear almost black. The right lung is streaked with slaty indurated cicatrices and almost devoid of air, but rather well supplied with blood. Several bronchiectatic cavities are present. On the contrary the pigmentation of the left lung is a little less, as also are the indurations, but there is some marginal emphysema. The bronchial and tracheal lymphatic glands at the base are enormously enlarged; several of them are strongly indurated and black, and are adherent to the bronchi and the surrounding vessels, the walls of which are more or less streaked with anthracotic pigment. A larger black lymphatic gland is adherent to the principal branch of the vena pulmonalis, the wall of which is very strongly colored with coal pigment. An incision into the vena pulmonalis discloses an opening at the point of junction. In the liver and spleen there is a bulky deposit of pigment. In the latter it can even be diagnosticated macroscopically. In the kidneys there is a smaller mass of black pigment within a degenerated glomerulus; this proved to be anthracotic pigment (See Fig. 5).

Case X.—Exquisite vesicular emphysema of the lungs. Anthracotic pigmentation of the lungs is marked. They are not especially indurated, the blood capacity is rather normal. The bronchial and tracheal lymphatic glands at the base are enlarged, indurated, and slaty; some are adherent to the vessels and bronchi, close to which they lie and the walls of which are streaked with black pigment. A larger black gland firmly adheres to the principal branch of the pulmonary artery. An incision discloses a small opening which leads into the interior of this gland. In the liver and spleen there is a deposit of black anthracotic pigment.

Tuberculosis in London.—Notwithstanding its fogs and supposedly unhealthful climate, London has a lower mortality from tuberculosis than many other European capitals. In 1904 it was only 166 per 100,000 inhabitants, as against 257.5 in Berlin, 254 in Milan, 256 in Madrid, 314 in Vienna, 383 in Paris, and 387 in Moscow.

PROSTATIC CONCRETIONS, WITH SPECIAL REFERENCE TO ETIOLOGY AND TREATMENT.

By JOHN M. THOMPSON, A.B., M.D.,

BOSTON, MASS.

For many years contributors in the domain of genitourinary literature have had a noticeable predilection for the prostate gland; and while no part of the reproductive apparatus occupies a more conspicuous place in the current journals of the healing art to-day, still, in many respects the prostate remains an enigma. Among the various morbid processes associated with this gland,—which may be regarded as a barometer of the male generative function,—that of calculus is the one least determined and no doubt least familiar to the reader. For this reason the writer deems it a privilege to be able to report a very interesting and, it is to be hoped, equally instructive case, and to offer some remarks in connection with its etiology and treatment.

Etiology.—Among that large variety of functional nervous disorders which the late Dr. Beard classified under the central title of neurasthenia, the one commonly found in man was of a sexual type, in which the prostate was invariably a factor to be reckoned with. Beard's tireless investigations and profound study of this disease established the fact that it results from modern civilization, with its attendant excesses, indiscretions, and short cuts to the goal of ambition in all walks of life. For our purposes, it is merely essential to know that neurasthenia in the male is likely to be of sexual form, and the degree to which it has developed is determined generally and positively by the anatomical and physiological conditions of the prostate gland.

In the face of so many other problems pressing for solution from the viewpoint of the new school established by Pasteur, Lister, Koch, and others, it it not to be wondered at that calculi of true prostatic origin should be passed over slightingly; but when such eminent authorities as Sir Henry Thompson, Posner, Stein, and others, give assurance that this form of calculus is commonly found in the prostates of middle-aged and old men, and not infrequently during youth, surely, it behooves the physician to be on his guard.

In order to simplify matters, the causative factors may be divided into pathological and functional. Under the former are included all inflammations starting directly in the gland itself and indirectly from the extension of acute and chronic processes seated originally in other parts of the urogenital apparatus. The latter comprise the various agencies causative of derangement of function. Heredity, alcohol, climate, nationality, errors in mode of life—factors not to be overlooked in the formation of the more familiar forms of calculus, such as renal, hepatic, and vesical—all contribute to the causation of prostatic calculus.

It naturally follows, then, that since the prostate contributes the largest share of the secretion to the seminal fluid, the most important and direct factor in the formation of concretions in this gland is obstruction to the exit of its secretory product: the next formidable cause is retention. Inasmuch as the disturbance is associated with prostatorrhea (an excessive product), together with the fact that both obstruction and retention favor alkalinity, no doubt should obtain in the mind of the reader in regard to the probable outcome of these formative causes.

Symptomatology.—The cardinal signs of prostatic concretions seldom, if ever, betray themselves

subjectively during the early stage, in consequence of which fact the process may not be discovered until a comparatively short time before inevitable abscess formation. It devolves upon the physician, therefore, to look into the previous history, and to resort to an exploratory examination per rectum, should the proper opportunity present itself. Such history will disclose sexual weakness, with premature or deferred ejaculation, night emissions, fear of impending impotency, neurasthenia, fullness and throbbing in the rectum, with occasional spells of marked sexual ardor. Invariably the patient calls attention to something moving along the floor of the canal, and this proves to be the periodic escape of excessive secretion, known as prostatorrhea, pathognomonic and noticed after micturition and defecation. One should bear in mind, too, that these patients are subject to spells of melancholia, are in dread of complete loss of sexual power, and are disposed to brood over their hopeless future and to isolate themselves from society and even personal friends.

In the absence of sufficient evidence upon which to establish a diagnosis, however, one may resort to the microscope. Cylindrical cells, amyloid bodies, lecithin, and the characteristic Boettscher's crystals will remove all doubt as to the existence of prostatorrhea.

Composition and Unique Features.—Unlike the more familiar forms of calculi, as found in the liver, kidneys, and bladder, the true prostatic calculus is smaller, ranging in size from a small seed to a large bean, and far different in shape as well as in composition. At first they conform to the follicular cavity, but later, when the walls of adjoining follicles break down, two or more small concretions unite, forming an irregular, shell-like mass of a chalky, friable, and brittle consistency—qualities peculiar to their alkaline formation. Inasmuch as they result from the precipitation of constituents in the gland's secretion, they are composed of calcium, sodium, and ammoniomagnesium phosphates, together with granular detritus.

Treatment.—At the outset, let it be said that in calculus of the prostate the physician has an exceptional opportunity of employing the ounce of prevention that is better than the pound of cure; that while the therapy of this process is curative and expectant as well as preventive, successful results are to be looked for only by the administration of prophylactic measures. But no matter to what stage one may chance to find the process developed, three essential facts must be borne in mind, namely, (1) obstruction to the exit of the gland's secretion; (2) consequent retention; (3) persistent alkalinity. Accompanying these conditions one is likely to find a phosphatic, alkaline, fetid urine, charged more or less with bacteria.

In order to meet the above wants by proper and efficacious remedial measures, the two methods of treatment that suggest themselves are internal and local. The first calls for an agent capable of rendering the renal secretion acid, sterile, antiseptic,—in short an agent that will destroy every possible source of irritation and preserve the urine sufficiently to prevent all danger during the act of micturition; the second admits of whatever will serve the physician in overcoming obstruction and in eliminating the excessive product from which the concretions are formed.

Among the several remedial agents provided of late years in the materia medica of genitourinary disease the formaldehyde products have found the most general favor. In cases where an assured continuous antiseptic reaction was desirable, however, they have proved disappointing, in virtue of the small amount of the formaldehyde set free in the bladder; furthermore, in that large variety of urogenital disorders characterized by a fetid, strongly alkaline urine, they have failed to exert anything like the necessary therapeutic effect on the reaction. And when one considers that bacteria propagate in alkaline media and are inert in acids, it naturally follows that in order to promote as well as to preserve sterility in the urine, one must restore that acidity which Nature has provided to hold in solution those normal constituents that are not eliminated in an alkaline medium.

The scope of this paper will not permit of details in connection with therapeutic agents. Suffice it to say that the only preparation capable of liberating a sufficient amount of formaldehyde in the urinary tract, as well as of exerting the proper degree of acidity, is what may be called a reinforced hexamethylen-tetramin, formed by the addition of anhydromethyleno-citric acid to the latter. By reason of this acid larger quantities of formaldehyde are set free than when hexamethylen-tetramin is employed alone; furthermore, when the latter unites in the renal tract with a strongly alkaline urine such relatively small quantities of the formaldehyde appear to separate that one is scarcely able to determine its presence in the urine; hence it is that, as many observers failed to obtain any perceptible antiseptic or sterilizing effect from the drug, it became necessary to reinforce it. This reinforced hexamethylen-tetramin is readily soluble in water, palatable, and when given in doses of 10 to 15 grains diluted, will be found to produce a marked change in the urine within an hour. (Chemically known as hexamethylen-tetramin anhydromethylen citrate.)

After close observation of many patients who have required treatment for prostatorrhea, it has been noted that the great majority have had an accompanying phosphaturia resulting from that excessive metamorphosis of nervous tissue so characteristic of all chronic disorders of the prostate. In fact, these patients were disposed not only to void an alkaline urine, but showed a tendency to alkalinity on the part of other secretory organs. Hence, it follows that the employment of a remedial agent that not only sets free the desired amount of formaldehyde to ensure sterility, but one, especially, that exerts its full therapeutic action in neutral, alkaline, or acid urine, must be regarded as the *sine qua non* of internal therapy.

In this connection, however, one can well afford to employ in some cases such dietary precautions as tend to promote acidity of the secretions. When possible, preference should be given to preventive measures, such as the prohibiting of foods that encourage alkalinity and the use of the simple acids provided in lime juice and in fruits.

In order to remove the retained product and to overcome obstruction of the ejaculatory ducts, no form of treatment will bear comparison with massage. Unfortunately, however, owing to the insidious development of this process, the remedy is limited in its employment. But during the incipient stage, should this maneuver not prove irritating, it can be relied upon invariably to remove the locked-up product which is the direct cause of the calculus formation. Each prostatic lobe should be treated gently and cautiously once a week, and the length as well as the intensity of the manipulation by the index fingers must be determined by those conditions which experience alone enables one to infer from an examination of the gland itself, and from

a knowledge of the various factors which in each individual case conspire to affect prognosis no less than treatment. When by reason of the advanced stage of the process—when marked tenderness is complained of, and, for that matter, in the absence of tenderness, when the concretions are clearly perceptible to the touch—the safest course to pursue is the expectant, with constant internal medication, scrupulous watchfulness of the patient, and a thorough examination of the urine and of the escaping prostatic product.

In the event of inevitable abscess formation, the last-mentioned plan of watchfulness and expectancy should be carried out, if anything, more closely, so that the surgeon's knife may anticipate Nature, which, by moving in the line of least resistance, unfortunately in this particular lesion, selects the rectal route for evacuation, thus rendering more probable resulting ischiorectal involvement.

Should one be fortunate enough to find the abscess "ripe," so to say, and by a timely and generous incision in the direction of the perineal raphé, to provide proper drainage, success will follow in due course. Before operation it will be expedient to relieve the portal circulation by free catharsis, and, of course, to render the urinary tract sterile, as suggested above; after operative interference, antiseptic irrigation and the strict adherence to modern surgical technique will be rewarded by desired results.

Case Report.—A strong, robust business man, aged fifty-four, married, considerably overweight, exceptionally active and energetic; habits, discreet and systematic; a total abstainer from alcohol for years; of nervous and emotional temperament. Previous history of urethritis and resulting stricture, for which meatotomy and urethrotomy were performed seventeen years ago, with good results. Other history negative. Urethra has admitted Nos. 27 to 30 F. sounds since the operation for stricture. Although not excessive or indiscreet in his sexual relations for the past seven years, he has noticed a thin, transparent, sticky discharge oozing from the meatus. At first it occurred periodically, and finally became constant, aggravated by sexual indulgence. At times he observed, too, derangement of the sexual function, with lack of ardor and deferred orgasm, followed by a tickling sensation simulating a tenesmus in the deep urethra. On October 14, 1904, he consulted the writer for the first time, when he sought advice and relief for an almost constant pain in the lumbar region and for the discharge at the meatus, several drops of which product he could force out whenever requested. Digital exploration per rectum revealed a chronic prostatitis of a mild character, due, no doubt, to the free escape of the excessive prostatic secretion, or prostatorrhea. There was apparent tenderness to the touch; no nodules, and not the slightest suggestion of the presence of impacted calculi.

In this connection it is reasonable to state that the calculi which escaped four months later were in all probability present at the time of examination; whether or not they escaped notice by reason of the writer's absolute indifference to the existence of concretions at the time of examination, it is difficult to say. However, it is interesting to know that both lobes of the prostate were treated by massage each week up to January 1, 1905, with the result that the lumbar pain and prostatorrhea entirely disappeared, while at no visit did the patient complain of pain or even discomfort from the massage.

On February 14, 1905, while the patient was suffering from what looked like an acute grip, the writer was summoned to his home, where examination disclosed acute abscess of the prostate with acute cystitis. During the next three days suppression of urine occurred, followed by marked edema of the genitals and adjacent tissues. Prompt removal of the retained urine was called for, and on February 18, after almost superhuman efforts on the part of the family physician and the writer, relief came at last, but not until several bougies and flexible catheters of various sizes had been introduced, followed by a silver catheter. At first it was found impossible to enter the bladder by gentle means; when sufficient force was exerted to puncture the prostatic region pus escaped sparingly. The introduction of a wire stilette revealed an obstruction, which, after careful manipulation, was found to be due to the concretions, three of them passing through the catheter, the largest becoming impacted and necessitating withdrawal of the instrument in order to remove it. The patient now voided urine, though with intense pain.

On the following morning, February 19, a consultation with Dr. A. T. Cabot resulted in the removal of the patient to the Massachusetts General Hospital, where a free perineal incision was made, only to find the prostatic abscess nearly evacuated. Free drainage and irrigation hastened recovery in a few days and discharge in six weeks.

Since the patient has left the hospital the urethra has admitted as high as a No. 30 F. sound; discharge is now absent, and more remarkable than all is the freedom from discomfort in the deep urethra and the marked improvement in sexual vigor.

Diagram of calculi in the author's case.

Remarks.—Before closing this paper it seems pertinent to mention certain facts which have come to the knowledge of the writer recently, inasmuch as they may throw some light on the etiology of this particular case and possibly lend some help in connection with others.

According to the patient's own testimony, long before the appearance of the prostatic discharge, he began to carry out a course of treatment for the purpose of nipping in the bud unmistakable evidence of rheumatic gout. To this end, among other means employed, such as modification of diet, abstinence from alcoholic drinks, land and sea trips, attention to personal hygiene by hydrotherapy and bathing, he drank daily from one to two quarts of piperazine and other alkaline waters, the effect of which was to overcome acidity in the renal secretion. Although unaware that the patient was resorting to any artificial help, the writer recalls distinctly with what surprise he found the urine alkaline each and every

time he resorted to uranalysis during the two years preceding the formation of the prostatic abscess. He also recalls the successful outcome of two cases during the past year suffering with prostatorrhea and incipient calculus formation, with a previous history similar to the case reported, in which urinary antiseptics, massage, and the promotion of acidity of the urine formed the basis of treatment.

Apart from resorting to such precautionary measures in relation to food, drink, exercise, etc., as are negative, preventive, and helpful to the physician in his efforts to attain a desired result, it must be granted that general constitutional effects are expected and brought about by internal medication. For example, in acute and chronic rheumatism the salicylates produce a decidedly prompt and efficient curative effect; in malaria, too, the action of quinine is no less apparent and satisfactory. For similar reasons, it is reasonable to expect that formaldehyde set free in the bladder will be absorbed into the circulatory apparatus to a sufficient degree to increase and to preserve the normal acidity peculiar to the secretory products of other organs. Furthermore, in the light of the writer's,—to be sure somewhat limited,—experience and observation in connection with the remote therapeutic action of this particular remedial agent, the result has been to restore a mildly alkaline secretion to its originally normal, neutral, or slightly acid condition.

In properly selected cases of incipient calculus formation in the follicles of the prostate gland, cases permitting of local massage to relieve the retained secretory product and to overcome obstruction to its outlet, the restoration and preservation of even slight acidity by internal medication form the principal indications to be met on the part of the physician.

134 Huntington Avenue.

OPHTHALMIA OF THE NEWLY BORN.*

By J. CLIFTON EDGAR, M.D.,

NEW YORK.

The most important of the causes of blindness with which we have to do is that resulting from an infection of the eyes of the child at birth. Important—first because it is the most common cause of blindness; second, because it affects the young child, and a long lifetime of blindness may follow, and third, because it is preventable and curable in practically every case receiving proper care, and one of the most dangerous maladies to vision when treatment is neglected or delayed.

It is a veritable world plague. It occurs everywhere, and no country has yet succeeded in getting it under control. So widespread is blindness resulting from it that Magnus, who has made careful statistical studies concerning it, says that out of 2,528 cases of all ages of complete blindness in Germany, 10.88 per cent. were due to this cause.

In institutions the proportion is much larger. A committee of the Ophthalmological Society of the United Kingdom in 1884 estimated that about 30 per cent. of the persons concerned have lost their sight through the ophthalmia of the new born. While in Mexico ophthalmia neonatorum is said by Ramos to be the common cause of blindness, and 4,500, or 30 per cent. of the whole number are blind as a result of this preventable disease.

In the New York State School for the Blind, 30 of 149 pupils have lost their eyes from ophthalmia neonatorum, which is a rather smaller proportion than that found in institutions elsewhere. In the State of New York more than 600 now hopelessly blind from this cause might have been spared this dreadful calamity had simple prophylactic measures been employed at the day of their birth, while in the United States there are between six to seven thousand people who have been blinded by this disease.

For the four years preceding 1906 the annual proportion of new pupils entering New York State School for the blind who had lost their sight from ophthalmia neonatorum was a quarter of the whole number admitted, while of the class of 1905, in which there were more young children owing to the effects of your Commission to find them, over 26 per cent. of the whole had become blind, not one of whom needed to have lost his sight had simple prophylactic measures been employed.

This is a disease dependent upon an infection finding an entrance in the eyes of the child at or immediately after birth. Stephenson had shown that about two-thirds of all cases of ophthalmia in newly-born babies are due to the micrococcus of gonorrhea.* If the eyes are carefully cleansed at once, so that the infected secretion does not get within the lids—or if the germs be washed out with a simple solution before they have time to multiply—or if the virility of the microbes be destroyed by a solution which is in itself harmless in its effect on the eyes, the disease will not develop. But as one can never be sure that in inexpert hands the washing is complete and thorough, and as it is not easily performed, the latter method in every suspected case at least should invariably form a part of the toilet of the child.

As this disease occurs in about 0.5 of 1 per cent., or one in 200 of all births, and as the total number of births registered for 1906 in New York was 183,012, the frightful prevalence of the disease can be readily estimated.

It should be the purpose of the profession, therefore, to find and make known some agent which may be used by everyone who attends a case of labor, and to this end the American Medical Association, by means of a series of questions, sent out in circular form, has endeavored to determine the most efficient and most popular method.

As a member of the Committee on Ophthalmia Neonatorum, I sent out a large number of circulars relative to the prophylactic use of silver nitrate in these cases. The number of physicians replying was 113. Of these, 103 think that a solution of nitrate of silver is the most effective drug for the prevention of this disease, as well as the most inexpensive. In view of the fact that a 2 per cent. solution occasionally causes silver catarrh and that a 1 per cent. rarely does so, 94 thought it safer and better to select this percentage for recommendation.

In addition to these replies, a number wrote personal letters, from which I shall abstract the most important points. Seven physicians prefer argyrol and protargol, in solutions from 5 to 25 per cent. Four prefer boracic solution, one announced himself in favor of sterile water, and one other uses saline. Still another prefers boric-acid or salt solution, but thinks it dangerous to teach to medical students and the general profession. Four physicians think that the choice of method should be left to the doctor in charge of the case. Three would make it compulsory for almshouses, hospitals and dispensaries, but not for private cases. The 2 per cent. silver nitrate solution was preferred by three.

*Read before the American Gynecological Society, Washington, May 9, 1907.

*Ophthalmia Neonatorum, Its Etiology and Prevention. Transactions of the Obstetrical Society of London, Vol. XLV., 1905.

One goes on record as saying that he does not consider silver nitrate a prophylactic in all cases: another asserts that the vaginal canal always contains bacteria.

Incidentally, in reply to the proposition that a law be passed in each State securing the distribution through the various State Health Boards of small, sealed, inexpensive, light-proof, tubes or ampoules of the selected solution to be sent gratuitously to every physician and midwife on the passage of the law, and subsequently when required, or on filing of each birth certificate, 97 replies were in favor of such a law, 11 against it, and 5 were uncertain as to its advisability. Of the 11 opposing, 3 were not in favor of laws compelling physicians to perform an obvious duty.

In answer to the proposition that it shall be required by law that the birth certificate shall contain a statement signed by the accoucheur that some recognized procedure specified on the blank has been used in each eye of the newly-born on the day of birth, as a preventive of ophthalmia neonatorum; in the absence of this statement, should ophthalmia neonatorum develop, and the child lose the sight of one or both eyes, the accoucheur, whether physician or midwife, filing the certificate, shall be deemed guilty of criminal negligence, and shall be subject to such penalty as the State may exact. Eighty were in favor of such a law, 24 opposed, 5 were undecided, and 4 made no reply. Five remarked that this was too drastic a procedure, 1 considered the proposition none too strong, 5 remarked that it would bring physicians into trouble through damage suits, 1 thought it applicable for midwives and not for physicians.

In answer to the proposition that it shall be the duty of the State Health officers to place ophthalmia neonatorum on the list of communicable diseases, and failure of the attendant to report to the local Health Board each birth, the existence of ophthalmia neonatorum when present, and the fact that some prophylactic has or has not been used, shall be considered a misdemeanor, and subject the offender to such penalty as the State may exact. Ninety-one favored such a proposition, 16 were opposed to it, 2 were undecided, and 4 did not answer this question.

In answer to the proposition that it be strongly urged if the above program meets with general approval, that the president of each State Association be invited to appoint a Committee on Ophthalmia Neonatorum, whose duty it will be to collaborate with the State Board of Health in securing in the several States the enactment and enforcement of laws embodying the above propositions—97 were in favor, 9 against, and no answer was received from seven.

The conclusions from a study of these replies make it certain that silver nitrate as a 1 per cent. solution is preferred by obstetricians in the United States in a position to judge of the merits of the various measures employed.

An important objection to Credé's method is that it tends to increase eye morbidity by causing "silver catarrh." This has led to the use of argyrol and protargol. Zweifel uses the former and neutralizes with sodium chloride. His morbidity in over 5,000 cases has been but 0.23 per cent. Scipiades finds argyrol a certain prophylactic. From a number of other clinics come equally good reports as to protargol. Not only were the results less favorable, but more silver catarrh was caused by Zweifel's method than by any other single procedure. Hence, at the Hofmeier clinic, Credé's one per cent. is regarded as the best prophylactic.

My faith in the prophylactic power of the nitrate of silver method is so strong that I attribute all apparent negative or ill effects of the method to the presence of antepartum infection of the eyes, to unskilled application or to improper or inert solutions.

Does Credé's Method Cause Conjunctivitis?—Neither Leopold (in 3,000 cases) nor Rosthorn (in nearly 25,000 cases) ever witnessed this accident. Bischof maintains that conjunctivitis never results if technique is correct.

In regard to treatment, Alvarado sent out a circular of inquiry to colleagues (oculists) in all parts of the world as to relative merits of Credé's method on one hand and the substitution of protargol on the other. He received 31 replies, all but one in favor of Credé's. The exception was the Lyons clinic, where protargol is in use.

Ernst discusses Credé's method very briefly with reference to the conjunctivitis which it is said to cause. No gonococci are ever found in these cases. They are due therefore to the nitrate. He experimented with a 1.5 per cent. solution and still got the conjunctivitis. Finally he found that the one per cent. solutions were non-irritant. At the Cologne Maternity, from January 1, 1902, to July 1, 1904, Ernst employed the one per cent. solution in 1,111 births. Not a single case of ophthalmia developed.

The work detailed in this paper was performed for the purpose of determining, if possible, what strength of silver nitrate solution might be safely entrusted to the hands of students and midwives for the purpose of instilling into the eyes of the newly born in order to prevent ophthalmia neonatorum.

In considering this matter, the following characteristics were thought to be essential to the proper solution:

1. The solution must be one which will be germicidal to the gonococcus.

2. The technique of its application must be simple so that in the hands of the most careless or inexperienced student or midwife no harm can be done.

3. The solution must be of such strength that while it will prevent ophthalmia neonatorum it will not cause silver catarrh.

4. The solution must be stored in such a receptacle as (*a*) to preserve its strength, and (*b*) to permit of its being placed in the eyes of the newly born without possibility of mechanical injury.

1. *The solution must be one which will be germicidal to the gonococcus.*—The work of testing the germicidal effect of various strengths of silver solutions on the gonococcus was undertaken by Prof. James Ewing of Cornell Medical College. He assigned the task to Dr. John C. Torrey, one of his staff, the work being done in the Loomis Laboratory. Our thanks are expressed to both Drs. Ewing and Torrey for the complete report which here follows:

Test of germicidal effect of 0.5 per cent., 1 per cent., and 2 per cent. of silver nitrate on gonococus: Culture of gonococcus on ascitic agar 24 hours old was used in the tests.

1. Three drops of this growth was emulsified in 5 drops of sterile distilled water. To this was added 6 c.c. of 0.5per cent. silver nitrate (solution distinctly cloudy thereby). One large drop of this was

transferred to 15 c.c. ascitic broth tubes at the following intervals:

		Result 24 hours.	
I.	15 seconds ..	No growth.	Negative.
II.	30 seconds ..	" "	"
III.	45 seconds ..	" "	"
IV.	1 minute ...	" "	"
II.	Same operation with 1 per cent. silver nitrate:		
V.	15 seconds ..	No growth.	Negative.
VI.	30 seconds ..	" "	"
VII.	45 seconds ..	" "	"
VIII.	1 minute ...	" "	"
III.	Same with 2 per cent. silver nitrate:		
IX.	15 seconds ..	No growth.	Negative.
X.	30 seconds ..	" "	"
XI.	45 seconds ..	" "	"
XII.	1 minute ...	" "	"

Control. Distilled H_2O (sterile) used in place of nitrate solution:

XIII.	15 seconds	Growth.	Positive.
XIV.	1 minute.....	"	"

From these experiments it would appear that silver nitrate in 0.5 per cent. strength or stronger is quickly germicidal to the gonococcus.

2. *The technique of its application must be simple, so that in the hands of the most careless or inexperienced student or midwife no harm can be done.*—So far as I could learn from careful inquiry at a number of maternity hospitals, the general technique was to drop into the eye several drops of some silver preparation from a glass medicine dropper, and shortly thereafter to cleanse the eye with a second solution such as plain sterile distilled water, boric acid solutions of varying strengths, or normal saline solution, but nowhere could I find that a silver nitrate solution was used without immediately applying some other solution to neutralize or wash away the silver salt.

It would seem that it would be a dangerous practice to require the use of a preparation that necessitated after-neutralization for, in the various exigencies of the lying-in room, such after-neutralization or cleansing might be neglected or improperly performed and the eyes of a large number not infected with the gonococcus might be injured by the production of a silver catarrh. Therefore, if a solution which did not require after-neutralization could be supplied, a very simple procedure could be inaugurated thus: First, wipe the eyelids with a clean piece of gauze or cloth not previously used in the lying-in room. Second: drop into the eye the contents of receptacle containing the solution. This technique would be simple and, with proper receptacles containing just enough for one eye, would be perfectly safe. Furthermore, if it could be shown that some certain solution could be used with equally good results, whether neutralized or not, it would be the ideal solution. Then in case neutralization was neglected, the eye would still be protected from infection and no silver catarrh set up. Such a result seems to be found in the use of a solution of 1 per cent. silver nitrate, as is shown in the observations hereinafter recorded.

3. *The solution must be of such a strength that, while it will prevent ophthalmia neonatorum, it will not cause silver catarrh.* It was for the purpose of trying to find some solution which might be used without after-neutralization that would prevent ophthalmia neonatorum and at the same time produce no silver catarrh, that the following observations were made.

The cases observed were in the wards of the Manhattan Maternity Hospital and the Bellevue Emergency Hospital. The patients were from the average east side tenement-house district, some with histories of previous vaginal discharge, some with vaginal discharge on admission, and some with neither history nor sign of vaginal discharge.

The technique used in the eyes of the newly born from these patients was as simple as could be performed. In some cases as soon as the head was delivered, in others after the delivery was completed, with a clean piece of gauze the mucus was wiped from the eye and by means of a medicine dropper one to three drops of the solution were dropped into each eye. This method was followed out with solutions of silver nitrate of one-half of 1 per cent., 1 per cent., and 2 per cent., with the following results:

Solution	Subsequent Neutralization	Number Children	Result	Hospital
Silver nitrate, 1 per cent.	Boric acid solution.	1,000	25 cases mild silver catarrh longest reaction 3 days. No opthalmia.	Bellevue.
Silver nitrate, 2 per cent.	Nominal saline solution.	20	5 cases silver catarrh. Duration 2 to 3 days. No ophthalmia.	Manhattan Maternity.
Silver nitrate, .5 per cent.	No cleansing of eyes afterward.	35	No cases of silver catarrh; 1 purulent ophthalmia developed on 9th day. Treated argyrol 35 per cent.	Manhattan Maternity.
Silver nitrate, 1 per cent.	No cleansing of eyes afterward.	20	1 case silver catarrh. Duration 2 days.	Manhattan Maternity.
Silver nitrate, 2 per cent.	No cleansing of eyes afterward.	20	6 cases silver catarrh which yielded to boric acid solution in 2 to 3 days. No purulent ophthalmia.	Manhattan Maternity.

One thousand cases were treated at the Bellevue Emergency Hospital with a 1 per cent. solution of nitrate of silver, and this was immediately thereafter neutralized with a boric acid solution. There were no instances of ophthalmia neonatorum in this series. Twenty-five cases, or 2½ per cent., showed symptoms of mild silver catarrh, the longest duration of which was three days.

Twenty cases were treated at the Manhattan Maternity with a 2 per cent. solution of silver nitrate, and afterwards neutralized with normal saline solution. Of these five, or 25 per cent., developed silver catarrh, lasting from two to three days. No cases of ophthalmia neonatorum.

Thirty-five cases treated at the Manhattan Maternity with a 0.5 per cent. of nitrate of silver with no after-cleansing of the eyes. No case of silver catarrh resulted. One case of purulent ophthalmia developed on the ninth day, which was cured with 25 per cent. argyrol solution.

Twenty cases were treated at the Manhattan Maternity with a 1 per cent. solution of silver nitrate with no after-cleansing of the eyes. One case, or 5 per cent. developed a silver catarrh lasting two days. No ophthalmia.

Twenty cases were treated at the Manhattan Maternity with a 2 per cent. solution of nitrate of silver without after-neutralization. Six cases, or 30 per cent., developed silver catarrh, which yielded to treatment in two or three days. No purulent ophthalmia.

Of those cases in which one-half of one per cent. of silver nitrate was used, the eyes of 97 per cent. were perfectly normal after ten days, with no dis-

charge up to that time. A number of these were from mothers who had a purulent vaginal discharge on entering the hospital. The other 3 per cent. got up a purulent discharge about the ninth day and were then treated with argyrol and cold applications.

Of those cases in which 1 per cent. silver nitrate solution was used without after-neutralization, none of them had an after-discharge, with the exception of a blonde baby, which type of child appears to be more susceptible to the action of the silver salts than dark babies; at least this is the experience of the last seven years in the Emergency Hospital.

In those cases in which 2 per cent. silver nitrate solution was used the result was not so satisfactory. In the few cases tried a large per cent. showed signs of severe irritation, when the solution was not followed by boric acid solution.

The method which has most commended itself to the writer is the one now in use at the Emergency Hospital. It involves but one additional step in the technique, namely, that of following the installation of several drops of 1 per cent. silver nitrate in each eye, by a weak solution of boric acid. This method has been efficacious in several hundred cases, many of the mothers having been previously infected with the gonococcus. From the fact that a 1 per cent. solution may be used without after-neutralization, it would be perfectly safe to require the use of a 1 per cent. solution of silver nitrate, with after-cleansing by boric acid, and in the event of carelessness or negligence, even if the boric acid solution was not applied, there would no harm come to the eyes of the child.

4. *The solution must be stored in such a receptacle as (a)to preserve its strength, (b) to permit of its being used without possibility of mechanical injury.*—Ampoules, light-proof and hermetically sealed, as suggested by F. Park Lewis, M.D., in an article in the *Journal of the American Medical Association*, April 28, 1906, furnish something on the order desired.

Conclusions.—1. That silver nitrate solution of 0.5 per cent. strength when applied to the gonococcus for fifteen seconds or longer is germicidal to the organism. Therefore, any solution of equal strength or stronger would fill the requirements as far as germicidal power is concerned.

2. That the technique of administration consists simply of instilling the solution into the eye, requiring no after-neutralization.

3. That solutions of silver nitrate of 0.5 per cent. and 1.0 per cent. strength did not produce a silver catarrh, even though no neutralizing solution was used afterward. That solutions of 2 per cent. nitrate produced a silver catarrh in about 25 per cent. of cases, whether or not a neutralizing solution was used. Therefore a 1.0 per cent. solution, being germicidal and at the same time producing no silver catarrh, is recommended.

4. That some convenient receptacle should be used.

I wish to express my indebtedness to Dr. Raymond Hoobler of the Cornell Medical College for much valuable assistance in the preparation of this paper.

50 East Thirty-fourth Street.

The Risks of the Matutinal Drinker.—At an inquest held in an English city it was stated that there were signs of lead poisoning in the system of a man who had been a heavy drinker. The doctor explained that it was probably due to his having been an early-morning customer at public houses, as a consequence of which he would be served with the beer which had stood in lead pipes all night.

STERILITY IN THE MALE, ITS CAUSES AND SURGICAL TREATMENT.*

By FRANCIS R. HAGNER, M.D.,

WASHINGTON, D. C.

PROFESSOR OF GENITOURINARY SURGERY, GEORGE WASHINGTON UNIVERSITY, ATTENDING GENITOURINARY SURGEON, GEORGE WASHINGTON UNIVERSITY HOSPITAL AND GARFIELD MEMORIAL HOSPITAL.

AND

HOMER G. FULLER, M.D.,

WASHINGTON, D.C.

It is only in the past twenty-five years that the subject of sterility in men has been carefully studied and valuable conclusions deduced. In earlier years unfruitful marriages were always ascribed to the wife, who in many instances was subjected to needless gynecological operations and treatment. If a man seemed well developed sexually, and was able to copulate in a normal manner, and had what seemed normal ejaculations of semen, he was considered potent, and failure to have offspring was always atrtibuted to some abnormal condition in the woman.

With the advance in genitourinary surgery the condition of the semen and seminal tracts has been carefully studied, with the result of proving that in a considerable number of cases, where copulation was effected and the appearance of the semen was normal on microscopical examination, the fluid was found lacking in spermatozoa or else these cells were nonmotile or degenerated. As a net result of many investigations it may be stated, in general, that in cases of unfruitful marriages the husband is the sterile member of the family in about one case in six.

According to Kehrer, the cause of childless marriages is now sought much oftener on the side of man than has heretofore been the custom. Kehrer, himself, gives the results in a series of 96 cases. In 3.12 per cent. there existed inability to copulate. In these cases there had been a preceding history of excessive masturbation. The men suffered from frequent pollutions, or their ejaculations were premature, and the penis could not be inserted into the vagina. Kehrer claims that impregnation may occur if a speculum be inserted into the vagina before copulation, and in several cases results were obtained by this maneuver. In 21.31 per cent. azoospermia, absence of spermatozoa, existed. In practically all of these cases there was a history of gonorrhea with unilateral or more often bilateral epididymitis. Azoospermia was also found where no disease of the sexual organs had occurred, and where nothing abnormal in the genital organs could be demonstrated. Oligospermia, paucity of spermatozoa, was demonstrated in 11.45 per cent. Here there was a history of gonorrhea with epididymitis, or syphilis. It will be seen from this series of 96 cases that 63 per cent. of the sterile cases had a history of gonorrhea with infection of the epididymis and prostate. Noeggerath found 8 sterile marriages in a series of 14 to be the fault of the male. Gross in 192 cases found the male deficient in 18 per cent.

Sterility in the male is due (1) to aspermia, nonsecretion of semen; (2) to azoospermia, where the semen does not contain spermatozoa; (3) to oligospermia, where the spermatozoa are few in number; (4) to conditions where the spermatozoa may be motionless or the motility be transient, or (5) to obstruction to the passage of semen to the urethra or seminal vesicles, and the escape of semen outside

*Read before the George Washington Medical Society, Washington, D. C.

of the normal channels, as in cases of hypospadias and fistula. Men with double undescended testicles are almost invariably sterile; so, too, is this the case in those whose testicles have received serious injuries causing destruction of the secreting structure or traumatic occlusion of the efferent ducts. This latter is a condition which obtains in cases of epididymitis; the exudated lymph fails to be absorbed, and becomes transformed into contracting connective tissue, which results in an obliteration of the tubes of the epididymis. Furthermore, the mouths of the ejaculatory ducts may be occluded as a result of operation for stricture, stone, or prostatic conditions. In the cases of azoospermia, absence of spermatozoa, the ejaculated fluid will present all the physical properties of normal semen, as regards smell, consistency, and so forth. Where we have small calibered strictures, the fluid is either forced back into the bladder or retained in the urethra behind the point of constriction, until erection subsides, whence the fluid slowly dribbles out. A few cases have been recorded where none of the reasons cited would hold, but these have been explained by the belief that the semen was perverted in quality or deficient in quantity, through constitutional depression or cachexia. Here the microscope would repeatedly disclose a state of azoospermia or oligospermia with the few spermatozoa showing but feeble motion or else complete absence of motion. And after no course of treatment other than that for the cachexia we would eventually find the presence of the procreative bodies and soon hear of an impregnation. Then, too, we are forced to consider the theory of apparent lack of affinity of the one cell for the other; we see this demonstrated in cases of a childless first marriage being followed on both sides by marriages resulting in a large family for each member of the former union. We hear of the so-called physiological and psychological question with which the stockbreeders have to contend at times, and which forces them to set aside a prized stallion of known abilities for one of inferior pedigree.

Next to gonorrheal infections, frequent masturbation and sexual excesses are the most frequent cause of sterility in the male. The prolonged and frequent overstimulation of the secreting structure of the testicles finally results in exhaustion of the organ the spermatozoa being imperfectly formed, even though the quantity and quality of the fluid may be apparently normal. The virility of the spermatozoa is often in direct proportion to the general physical condition of the patient. The oft-repeated shocks to the nervous system, which occur especially in masturbators, who take advantage of the time and place which are always convenient for their purpose, lowers the general physical condition, producing constitutional depression and cachexia, and thus affecting the virility of the spermatozoa. I have seen several of these cases perfectly cured by leading a hygienic sexual life.

In bilateral syphilitic and tuberculous disease, a considerable proportion are sterile on account of the destruction of the epididymis in tuberculosis, and the destruction of the testicle itself in syphilis. Another cause existing in this modern age is the x-ray. Workers in x-ray laboratories and physicians doing this work are the ones affected. One prolonged exposure has been known to cause sterility lasting three months. At first the spermatozoa are dead, and later disappear altogether. I know of seven workers in an x-ray laboratory in New York who have been sterile for over a year. I do not believe that any permanent cases have been reported from this cause. It is too early yet to say. One worker of my acquaintance was sterile for some months, but after keeping out of the rays for three months this defect disappeared and his wife became pregnant. When inflammation has attacked the greater portion of the prostate, so as to block up the ejaculatory ducts, after an orgasm there may be two or three viscid drops escape that contain principally pus cells and degenerated prostatic cells, but no spermatozoa. In other cases there may be so much pus present in the prostatic and vesicular secretions as to cause the death of the spermatozoa when they come into contact with this element of the fluid. The diagnosis of this condition should be made on microscopical examination by finding pus and dead spermatozoa in the fluid obtained by massage of the prostate and seminal vesicles.

I have seen several cases where the spermatozoa were nonmotile that were cured by treatment of the prostatic condition, and in one case so much pus was present that part of the prostate was excised (care being taken not to injure the ejaculatory ducts); the pus disappeared and the spermatozoa regained their motility. The term false aspermia or malemission is sometimes employed to designate that condition in which normal semen is discharged into the urethra, but does not reach the meatus, flowing back into the bladder to be discharged drop by drop from the urethra after the completion of coitus. This is commonly due to stricture, the caliber of which may be great enough not to interfere with micturition, when the circulation of the penis is unimpaired, but when the intense congestion incident to erection takes place, the caliber of the urethra is so reduced that no semen escapes.

The following case shows this very admirably. J. H. W. came to my office in September, stating that he had gonorrhea eight years before and an internal urethrotomy three years later; following the operation patient nearly bled to death, as he is a hemophiliac. He had had double epididymitis six years previous, and when I first saw this case I thought it a case of sterility due to epididymitis. The patient collected semen in a condom; the amount obtained was very small and proved on microscopical examination to be nothing but mucus. He had not complained of difficulty in urination, but on examination a No. 12 French bougie was the largest instrument that could be passed. After gradual dilatation the fluid ejaculated during intercourse appeared normal in amount.

As I have heretofore mentioned, the principal cause of sterility in men is bilateral gonorrheal epididymitis. Benzler in the *Archives of Dermatology and Syphilis* in 1898, in looking up the history of old soldiers who had gonorrhea while in the German army, found that among those who had been married three or more years 10.5 per cent. who had suffered from gonorrhea without epididymitis were childless; these were probably the cases with chronic prostatitis and seminal vesiculitis; 23.4 per cent. of those having unilateral epididymitis, and 41.7 per cent. of those having bilateral epididymitis, were childless. It will be seen from all statistics that epididymitis is by far the most common cause of sterility, and it is most common in the cases where both sides were involved, almost 50 per cent. being sterile. Statistics show that traumatic epididymitis, unless very severe, rarely leads to sterility. Orchitis probably never occurs in gonorrheal infections. I say this from results in twelve cases that I have operated upon, with acute epididymitis of the severe type, in none of which was the testicle itself involved.

In epididymitis it is well known that the globus minor is the portion of the epididymis most involved, and it is in this very portion that occlusion has the most dangerous results, as there is here but one efferent duct, while in the globus major the efferent ducts are numerous, and the obstruction of one or two would still leave open other channels. It was because of the known patulency of the globus major following gonorrheal epididymitis, when the globus minor and vas deferens in this region became occluded, that the operation of anastomosis of the vas deferens and the globus major was considered. The prognosis for the return of spermatozoa in these cases, unless operated upon, is positively hopeless.

Dr. Quinby of Boston has done some experimental work on guinea-pigs. He tied off the vas deferens at its exit from the globus minor, and then made an anastomosis between the globus major and the vas above the ligation, in the method recommended by Dr. Martin of Philadelphia (which is described later). Instead of using fine silver wire, very fine silk was employed.

In from 10 to 27 days three out of four of the pigs thus operated upon showed spermatozoa in the fluid ejaculated by means of electrical stimulation.

Two cases of sterility (following double gonorrheal epididymitis) under my care came to operation, one at the hands of Dr. Martin of Philadelphia, the other my own. In both instances Dr. Martin's method of procedure was employed, which I will describe. An incision is made through the skin and coverings of the epididymis, which is approached from the outer side so as not to wound the spermatic artery. The artery of the vas is pushed aside and a one-half-inch incision is made in the vas deferens on the level with the globus major, along its axis, care being taken to get into the lumen of the tube. A portion of the globus major is picked up between two fine forceps and an elliptical piece removed to correspond with the incision in the vas deferens. An examination of the fluid obtained by squeezing the globus major will show spermatozoa. Four fine silver wire sutures on curved intestinal needles are inserted, one at the upper angle of the wound joining the vas and the cut surface of the epididymis, one at the lower angle, one at the outer, and one at the inner side. When these are drawn out a perfect little pocket is formed by the spreading out of the cut vas deferens, and the elliptically cut globus major. The wound is then closed and dressed. It will be seen that the operation is not one of grave danger to life. It is one in which the existing condition cannot be made worse, but where, in fact, everything is to be gained and nothing to be lost. The first case was one referred to me by Dr. Wellington. The patient was a robust appearing man of thirty-eight, who had been married several years. His wife had been examined and no cause for sterility ascertained. He had had gonorrhea with double epididymitis some years before. Frequent examinations of the spermatic fluid showed no spermatozoa, but the fluid obtained was loaded with pus. The prostate and seminal vesicles had been the seat of chronic inflammation. The patient was operated upon by Dr. Martin, and the examinations after operation revealed live spermatozoa. This patient's wife has not given birth to a child, but has possibly succeeded in having a miscarriage.

T. D., twenty-nine years old, was first seen by me in February, 1905, being referred to me by Dr. Wall. The patient was a robust, healthy man of 235 pounds; he had had gonorrhea two years before and a double epididymitis three weeks later. There were numerous shreds in both urines. Examination revealed a large soft prostate and markedly enlarged soft vesicles; the fluid expressed by massage showed numerous pus cells. Patient was treated for six months, by which time the shreds had disappeared and the prostatic and vesicular fluid was free of pus. He was then married, and returned in about six months, complaining because his wife had not become pregnant. Dr. Thomas Kelley had been attending the wife, and said she was normal in every way. Examination of his semen showed no spermatozoa. It was thought possible that the absence of spermatozoa was due to frequent coitus. He abstained from coitus for two weeks and the semen still failed to show spermatozoa. He was kept under observation for two months, and repeated examinations proved the absence of cells that could possibly have been spermatozoa. He was advised, and consented to undergo an operation for anastomosis of the vas deferens and epididymis as his only chance for improvement. This was done one year ago at Garfield Hospital; recovery was uninterrupted, and he left the hospital in one week. Examination in one week showed no spermatozoa, but another examination a month after operation disclosed their presence in numbers. An examination of the semen on April 10, 1907, over a year after operation, showed the fluid filled with actively motile spermatozoa. So far no pregnancy has resulted in this case, but I continue to hope. Very few of these operations have been reported.

Dr. Martin has recently reported seven cases, four cases where spermatozoa appeared after operation, two cases not heard from, and one failure. One patient included in the four successful cases is the father of a healthy child. In some of Dr. Martin's cases the spermatozoa did not appear at once after operation, and in my case the spermatozoa did not appear until nearly a month. I believe this is accounted for by the slight inflammatory reaction following the operation causing occlusion of the vas deferens which disappears as the inflammatory exudate is taken up, thus allowing the vas and the ducts of the globus major to become patulous.

We know that after this operation in the majority of cases spermatozoa return to the fluid, and there seems no reason why fecundation should not take place. I might do well to quote Dr. Quinby's ending to his paper. The three main facts for employing this operation are: (1) The condition cannot possibly be made worse by operation; (2) there is double chance for success, as patency on one side is sufficient; (3) the operation has been found feasible.

1725 N Street.

Twisting of the Cord About the Neck of the Fetus.—Teobaldi Soli formulates the conclusions arrived at as a result of the review of the histories of 570 cases of twisting of the cord about the neck of the fetus seen at the maternity hospital at Turin. The condition is most unfavorable to the child. Its determining causes are deficient development of the fetus, too much amniotic fluid, and exaggerated movements of the fetus. Predisposing causes are primiparity and length of the cord. The condition is most frequent in posterior positions, and face presentations are very unfavorable. The size of the pelvis has little to do with this condition, but deformity by causing delay may be fatal to the child. Unfavorable factors are several turns made by the cord about the neck, as many as eight having been observed, marked development of the child, and length of labor. The danger to be feared is compression of the cord with interruption of the fetal circulation. The treatment is quick delivery by artificial means.—*Annali di Ostetricia e Ginecologia.*

New York, August 10, 1907.

PUBLIC HEALTH IN GREAT BRITAIN.

DURING his visit to this country in the early summer Dr. Osler, late of Baltimore, was a guest of the Philadelphia Pathological Society at its semi-centennial meeting. In the course of an address which he delivered at that time, he took occasion to inveigh against what he called the backwardness or non-existence of preventive medicine in this country, and compared it in very uncomplimentary terms with what he seemed to regard as the perfection of public health administration in Great Britain. It appears, however, that the English in general are not so pleased with existent conditions as is the new Regius Professor of Physic at Oxford. Dr. Ronald Ross, writing in *Nature* of June 13, implies that British medical administration in India could hardly be worse than it is, and in Great Britain itself there is a feeling abroad that all is not as it should be in regard to the physical, and, it may be added, the mental, condition of the nation at large. Perhaps, all the countries of the old world are awakening, not without cause, to a sense of their physical and mental shortcomings, but in England the feeling is intense. Various public speakers in different spheres of life have on recent occasions inveighed against the apparent decadence of the British race. Among such speakers medical men have been somewhat prominent, some of these indeed having been unsparing in their denunciations of the defective manner in which the rising generation of Great Britain is being brought up.

The annual Congress of the Royal Institute of Public Health of Great Britain was held recently. The chair was taken by Sir James Barr, who, it may be remembered by those of our countrymen who visited Toronto last year for the meeting of the British Medical Association, delivered the very excellent address in medicine at that time. On taking the chair he made a very startling speech, and, although some of his points were perhaps overdrawn for oratorical effect, still his arguments in the main may be taken as founded upon fact.

In the course of his speech the Liverpool physician said that if the money spent in the treatment of disease were diverted to the preservation of health our large hospitals would not be half filled, purveyors of patent remedies and artificial foods might find a suitable place in homes for the destitute, the necessity for surgeons and specialists would largely disappear, and physicians and general practitioners would be fully occupied in advising their clientèle on the preservation of health.

In reference to artificial selection, the speaker said that it was possible to have some such process of selection in the human race, and the nation which would produce the finest race would win in the long run. He proposed that millionaires should be very heavily taxed in order to provide ample funds for the aged, and he went on to say that huge trusts and millionaires were a positive danger to society. The former, he thought, should be rendered illegal, and every time the latter accumulated a million he should be relieved of half of it. He advocated the regular medical inspection of all schools and school children. As a nation, care should be taken that healthy children received proper attention as well as the halt, the blind, and the degenerate. In conclusion, Sir James Barr said that he could scarcely finish without referring to the mania for operations in the present day. He had no fault to find with surgeons generally, as they frankly admitted that preventive medicine was no part of their business, but it was a great blot on preventive medicine that so much surgery should be necessary.

The condition of the young in London has aroused considerable alarm during recent years, and a few weeks ago efforts were put forth in the direction of checking one of the most serious causes of infantile mortality and ill health, which is so conspicuous a feature in the life of the British metropolis. Drunkenness among women is the cause to which allusion is made, and especially the pernicious habit of taking infants in arms to saloons and giving them stimulants. This evil has grown to alarming proportions in London, and, according to good authority, is a potent source of much mortality, bad health, and degeneracy. Distinguished physicians and leading men in other branches of life have taken the matter up, and measures are being set afoot with the end in view of invoking the aid of legislation to abate the evil.

Although in Europe generally, and perhaps in Great Britain in particular, the conditions of life in certain sections of the large towns are inimical to life and health to a greater degree than in this country, yet we must not unduly plume ourselves that we are altogether free from similar defects in our large cities. True it is that drinking among women in public resorts is infrequent in America, and that spirit-drinking by women in such places is practically unknown, while the custom prevalent among a part of the London female population of taking infants in arms to saloons and giving them strong drink is absolutely unknown on this side of the Atlantic. However, in many respects, the care of the public health in most American cities is greatly neglected, and in various points London will compare favorably with most places in this country. In so far Dr. Osler's remarks were perhaps nearly true, even though lacking in taste, if not in courtesy to his hosts. Yet, on the whole, the health administration in this city is little, if at all, behind that of London, and in some respects it is decidedly superior. Preventive medicine, that is to say, the use of every conceivable precautionary measure to ward off disease, is the medicine of the future, and although the day is still far distant when preventable disease will be a thing of the past, yet the strict care of the public health is the longest step in that direction.

PREVENTION OF POST-OPERATIVE THROMBOSIS.

Under normal conditions thrombosis takes place in all injured or ligatured vessels that do not close by contraction or retraction, or by the elastic pressure of surrounding tissues. In an artery the thrombus forms on the cardiac side of the injury, between the latter and the branch last given off by the artery. If it progresses beyond this point, small emboli may become detached and cause gangrene around the periphery of the artery they lodge in; this occurrence, however, is rare, as the extension has to take place against the blood current. In a vein a thrombus may form in the centripetal or distal end of the injured vessel, or in both. In the centripetal portion the thrombus extends only to the point where the vein, which has been cut out of the circulation, empties into the vessel of which it was a tributary. The blood current in the latter prevents its extension under normal conditions; the thrombus is cut short, being a simple healing thrombus causing no symptoms. If it is not cut short we get a progressive thrombus extending in the direction of the blood current, the kind from which emboli are usually broken off. Progressive thrombi are therefore nothing but an exaggeration of a normal process, a dangerous condition arising out of a normal healing process.

The existence of a progressive thrombus is easy to diagnose in an extremity, where it manifests itself by pain, swelling, and palpable veins; not so when it occurs in the abdomen where it usually causes only vague symptoms, which are frequently attributed to intestinal disturbances, the real condition not being recognized until embolism itself sets in. A gradual daily increase in the pulse rate, with normal temperature, is a valuable diagnostic sign when present. Embolism affecting the pulmonary artery, right heart, or a large branch of the pulmonary artery is easily recognized. If, however, very small pulmonary vessels are involved the symptoms of the resulting infarct are somewhat vague; we may not even get bloody sputum, and pleuritic symptoms alone may be present. The condition is then hard to differentiate from mild lung conditions, as we see them after operation, as a result of narcosis, or after exposure to cold; hence whenever slight pulmonary symptoms arise the possibility of progressive thrombosis with embolism must always be borne in mind.

Little can be done when a thrombus has become progressive, and still less when embolism sets in; the treatment then consists only in cardiac stimulation and absolute rest, unless the thrombus has become infected when surgical procedures may be resorted to. Our main hope lies in prophylaxis, as Witzel has pointed out in the *Deutsche Zeitschrift für Chirurgie,* No. 85, 1907. He bases his treatment upon the general causes of intravascular coagulation. After a sudden profuse loss of blood coagulation takes place more easily, hence hemorrhage predisposes to progressive thrombi; in a similar manner infections of simple wound thrombi and contusions of veins predispose to them. Good hemostasis, little handling of tissues, and asepsis are therefore necessary at all operations. Virchow has pointed out that a poor circulation may cause thrombosis in uninjured veins, and much more easily must coagulation take place on top of a simple wound thrombus which projects into a weakened and slowed circulation. A poor circulation may be caused by weak action of the heart, as we find to be the case in chronic anemia, etc.; hence everything must be done to keep up a good cardiac action; stimulants must be given before, during, and after operations if necessary; ether is preferable to chloroform narcosis; the operating table should be warm; hot pads should be used in the wound and hot bottles placed around the patient when he is put back to bed. It is, however, not the heart's action alone which keeps up a good circulation, contraction of muscles, the prelum abdominale peristalsis, and deep inspirations all aid in a good venous circulation, but it is just these which are put to rest in the post-operative treatment of most surgeons, partly because the patient is thus kept free from pain, and partly because rest and quiet are deemed necessary for the good healing of wounds. This may be true, but Witzel considers activity no drawback to healing, and the best prophylactic treatment we have against the formation of progressive thrombi. His patients are therefore permitted to get up as soon as possible after operations, after amputations of the breast on the first day, and after laparotomies on the second, third, or fourth day. When it is impossible to get the patient up early he recommends systematic breathing exercises, active and passive movements of the extremities, and massage. As tympanites disturbs the portal circulation and prevents deep breathing, cathartics are given early, in other words everything is done to exercise the natural functions of the body immediately after operation.

Framboesia Tropica.

While there are still many differences of opinion in regard to this curious disease of the tropics, little by little some of its mysteries are being cleared up. Castellani's discovery that the lesions of the disease regularly contain a spirochete which morphologically cannot be distinguished from the *Spirochæta pallida* has been corroborated by numerous other observers. Castellani considered that syphilis and framboesia were different diseases, and therefore gave to the organism he discovered in the lesions of the latter the appellation *pertenuis seu pallidula.* Huchinson and Scheube were of the opinion that framboesia represented a modified form of the disease, but this view has not met with universal acceptance, and notably the inoculation experiments of Baermann and Halberstädter on monkeys appeared to prove that the diseases are not identical. Some observers go so far as to disclaim for framboesia all relationship to syphilis, and look upon it simply as an infectious disease running its course purely as a local cutaneous affection. Schüffner (*Münchener medizinische Wochenschrift,* July 9, 1907), who has studied the disease during five years of practice in Sumatra, believes that many of these differences of opinion depend on insufficient periods of observation, and says that he now has a very different idea of the disease from what was the case some years ago. In 129 cases of framboesia studied during the past six months he found the *Spirochæta pertenuis* 104 times, or in 81 per cent. of the cases. He has reached the conclusion that the disease is infectious and that the contagion is transferred by contact

through some cutaneous lesion. While the course of the disease presents many analogies to that of syphilis considerable differences exist, notably in the character of the cutaneous eruptions and in the fact that lesions of the mucous membranes never occur, so that the identity of the two diseases cannot be upheld. Bone changes and a peculiar ossifying form of periostitis are particularly characteristic, and in many respects frambœsia manifests itself as a very complex condition. In its course it exhibits a striking parallelism to syphilis, and Schüffner thinks it is to be considered an independent disease, a sort of second syphilis, the two conditions having somewhat the same relation as tertian malaria has to the pernicious form.

Spontaneous Lesions of the Cervix in Abortion.

The discovery of a recent injury of the cervix in a woman in the process of abortion would, if the lesion were at some distance from the cervix, lead the examining physician to conclude that it was the result of an unsuccessful criminal attempt to empty the uterus. Even if the patient were already under the care of a physician the suspicion would be aroused that a no doubt justifiable but technically imperfect operative procedure had been undertaken. Several cases are on record, however, in which such lesions of the cervix appear to have been spontaneously produced, and Blumreich reports another in the *Berliner klinische Wochenschrift*, July 15, 1907, in which there is no doubt that the cervix was severely damaged as the result of peculiar local conditions. When first seen in consultation by the author the patient, who was a young primipara in the fourth month undergoing an abortion induced on account of a recurrence of previous attacks of appendicitis, gave no evidence whatever of any cervical injury, the only procedure that had taken place having been the introduction of a strip of iodoform gauze into the cervix. This was extremely rigid, and after slight further dilatation with Hegar's dilators a laminaria tent was introduced without occasioning further trauma. Some hours later exceedingly violent pains set in, and when the author examined the patient at the expiration of twenty-four hours it was found that the posterior half of the cervix had been completely torn away from the vaginal vault, while the fetus was projecting from the uterine end of the cervical canal. Blumreich explains the occurrence of this injury through the fact that the cervix was unusually undilatable, so that the very violent uterine contractions finally caused its upper thinned-out portion to tear through. Cases of this sort are undoubtedly very rare, but it is well to keep in mind that they may occur without any foregoing improper manipulation, a fact that may be of importance from the forensic standpoint.

The Importance of the Rectum in Gynecology.

Men with practical experience in this field are unanimous in their declaration that an intimate relation exists between the state of the rectum and the diseases peculiar to women. Current literature and textbooks on gynecology strangely enough make little mention of this fact, and it may be quite safely assumed that there is corresponding deficiency in the teaching of students in this respect. As pointed out in an article by Pantzer (*American Journal of Obstetrics*, November, 1906) there exists a clear anatomical and physiological relationship between the rectum and the female genitalia, so that any variation in the function of one is communicated to the other. In susceptible individuals this disturbance may border closely on the pathological. Thus it is a well-known fact that the excitation of the rectum during menstruation may result in diarrhea or constipation sufficiently marked to require attention. On the other hand, chronic constipation may likewise affect the quantity, frequency, and course of the menstrual flow. A number of pelvic conditions have also been described in which such interdependence between these two anatomical entities is evident, and greater attention should therefore be paid to the part which the rectum may play in the clinical picture. It is of distinct advantage, therefore, to place the rectal examination on a par with the vaginal in a given case of pelvic disease, and Pantzer also calls attention to the importance of rectal medication in such cases. As the remedies are absorbed by practically the same lymphatic channels which carry the bacteria and the various toxins, it is believed that the former thus exert a direct antitoxic and diluent effect upon the morbific bacteria. Rectal medication and feeding have undoubtedly been overdone, but there is no question that a distinct field exists for these procedures, and this will be extended as the intimate relation between rectum and female pelvic organs, already referred to, becomes more generally recognized.

Medical Attendance at Duels.

The presence of one or more surgeons has long been considered an essential feature of a duel conducted with due respect to the rather complicated code that is supposed to confer a certain pseudo-dignity to such affairs, and it is to be presumed that the medical men who have given their services on such occasions have troubled themselves very little in regard to the ethical or moral considerations involved in their attendance. It is clear, however, that the matter should not be passed over so simply, and that there may well be differences of opinion in regard to the propriety of a surgeon's appearing to sanction the method of settling personal disputes, for while it is the medical man's duty to relieve suffering and to accord the benefits of his art to any injured person, no matter what may be his own convictions in regard to the manner in which the traumatism was received, this obligation hardly requires him to attend a duel in the expectation that a patient will be provided for him to treat, or that the necessity for signing a certificate of death will arise. This is the stand taken by the medical society of Palermo, which has decided that its members will in future refuse to officiate in this capacity, and several other medical organizations are said to have expressed similar intentions. Perhaps the knowledge that medical aid could not be counted on except in the ordinary course of events would serve to reduce the number of encounters on the "field of honor" that often spring out of trifles, but end seriously or fatally for one or both contestants, and it would seem very desirable for medical societies in all countries where the conditions require it to follow the example set by this Italian organization.

The Time for Brain Work.—Hallopeau of Paris, in speaking of brain workers, advised them to take a nap after lunch and a long sleep after dinner. He suggested that a good plan would be to prolong the latter rest to about 1 o'clock in the morning, when a man could wake up fresh and be in the best disposition for furnishing three good hours of intellectual work.

News of the Week.

Veto of the Optometry Bill.—Governor Hughes, on July 26, vetoed the optometry bill, officially known as "An act to amend the public health law by defining optometry and regulating the practice thereof." In the memorandum filed with the bill, the Governor says: "It is the intent of this bill that the board of examiners in optometry to be appointed by the Board of Regents shall be selected from those nominated by the Optical Society. It is also provided that the prescribed course of professional study in schools of optometry shall be had in such schools as maintain a standard satisfactory to the board of examiners. These provisions remove from the jurisdiction of the Board of Regents matters which it is important should be placed in their control. If the practice of optometry is to have the recognition and regulation contemplated by this bill the appointment of examiners should not be limited to those nominated by a particular society, and the determination of the standards of professional schools should be unequivocally left to the proper State authority. This is the policy established by the law enacted this year regulating the practice of medicine, and in my judgment it is unwise in legislation along similar lines to adopt a different principle."

An Anti-Meningitis Serum.—It is reported from Castalia, Ohio, that Dr. Simon Flexner of the Rockefeller Institute in New York, has elaborated a curative serum for the treatment of cerebrospinal meningitis. This serum has been administered with striking success, it is said, during an epidemic of the disease in the Ohio town.

New Rule Governing Vaccination in Pennsylvania.—By the action of the Advisory Board of the Pennsylvania State Health Department a person who has been vaccinated unsuccessfully three times, at intervals of two weeks, may for the time being be considered immune to smallpox. Further, persons that have a written certificate from a registered physician that two such attempts to vaccinate have been faithfully made, and a second certificate from a physician of the State Department of Health or a board or bureau of health, or a sanitary committee of a city or borough, may be admitted to school for one year without violating the spirit of the law, the object of which is simply to prevent the spread of smallpox.

Intemperate Legislation in Georgia.—Both houses of the Georgia legislature have passed an unusually drastic bill prohibiting the manufacture and sale of alcoholic beverages, and the Governor has affixed his signature, making it a law. Under the provisions of this bill no whisky, wine, beer, or other intoxicating beverage can be legally sold in the State after January 1, 1908. The liquids named are absolutely barred, but provision is made whereby licensed druggists may sell and furnish pure alcohol for medical purposes only upon written prescription of a legally practising physician. The bill requires that no prescription calling for alcohol shall be filled except upon the day upon which it is dated and issued or upon the following day. Within ten days after the same is filled by the druggist he shall file the prescription for record with the ordinary of the county in which it is filled. The record containing such prescription shall be open to public inspection. Upon any prosecution under this act the burden of proving the defence that the sale was of pure alcohol under prescription shall be upon the defendant. No druggist who is also a practising physician will be permitted to fill his own prescriptions, nor can they be filled at any drug store in which the said physician is financially interested, and no prescription shall be refilled.

Christian Scientist Sentenced to Imprisonment.—The Court of Special Sessions has sentenced to thirty days in the penitentiary the father of a six-year-old child, who allowed her to die of bronchopneumonia without medical aid, trusting in the efficacy of Christian Science treatment. The man's conviction resulted from his own admission. He confessed on the stand that he did not believe in medical treatment or in the use of drugs, and asserted his belief that only prayer healed. He was charged with violation of Section 288 of the Penal Code, which makes it a misdemeanor for a person willfully to omit, without lawful excuse, to perform a duty by law imposed upon him, to furnish food, clothing, shelter, or medical attendance to a minor. The Christian Scientists have announced their intention of using every resort to have the judgment reversed, while the District Attorney's office considers the decision of great importance, and will oppose such action vigorously.

A Lost Diploma.—A physician of Omaha, Neb., four years ago submitted his Harvard Medical School diploma to the Nebraska State Medical Board at Lincoln. It was shipped back to him by express, but never reached him, and as the college refuses to issue a duplicate diploma the doctor is suing the express company for $20,000, alleging that the loss of the diploma will prevent his practising in any other State.

Bellevue Patients to Pay.—The board of trustees of Bellevue Hospital has made a rule providing that any patient who has more than $50 value in his possession when taken to Bellevue and Allied Hospitals may be charged $1.50 a day for treatment in the institutions. This charge will be continued only until the person is reduced to $50. The rule was made in order to protect the needy poor, as it was found that many persons were occupying beds in the hospital who could well afford to pay for treatment.

Physician Sues Apartment-House Owner.—A Newark physician is suing the landlord of an apartment house for $5,000 damages on account of an alleged attack made upon the physician because he entered the apartment building through the front door. The physician was called to see a patient in the house, but the owner happened to be in the hallway, and a controversy arose as to the right of a physician to enter by the front entrance instead of by the servants' and tradesmen's door, the landlord finally assaulting the doctor. Efforts are said to have been made in other cases to compel physicians to enter by the back doors when making calls on patients living in apartment houses.

Railroad Fatalities in This Country.—The Interstate Commerce Commission has given out the statistics relating to the casualties to passengers and railroad employees during the quarter ending March 31, 1907. The total number during this period was 20,563, as compared with 20,944 reported in the preceding three months—a decrease of 381. The total number of passengers and employees killed in train accidents was 421, and the number of injured 4,920, 53 less in number killed and 20 less in the number injured, as compared with the record of the preceding three months. The total number of collisions and derailments in the quarter was 3,091 (2,078 collisions and 1,913 derailments), of which 323 collisions and 229 derailments affected

passenger trains. The damage to cars, engines, and roadway by these accidents amounted to $3,536.110.

Registration of Communicable Diseases in Pennsylvania.—A rule has been adopted by the Advisory Board of the Pennsylvania State Board of Health requiring physicians in rural districts to report every case of communicable disease under their observation to the township health officer, who will arrange for the necessary isolation and protection of the community from infection.

First Aid Instruction for Railroad Employees.—The employees of the Pennsylvania Railroad, numbering 198,000, are to be given a course of practical instruction in first aid to the injured. For this purpose a series of lectures will be delivered at various points along the lines under the direction of the company's medical examiner.

A Refuge for Victims of the Sleeping Sickness.—Philanthropy has seldom been more nobly illustrated than by the Roman Catholic missionary station at Saint Trudon on the Congo. For three years this mission has paid to the natives one franc for every sleeping sickness patient brought to it. The unfortunates were being driven from the villages to perish in the forests when humanity interposed to assuage their sufferings, even though their lives could not be saved. The Catholic fathers and sisters are still attending them in the hospital enclosure they provided, and every victim of the dread disease is made as comfortable as possible and receives a decent burial at the end.—*The Sun.*

An Increase in the Size of the Coming Race?—At the meeting of the British Medical Association at Exeter last week, Sir Victor Horsley spoke in favor of making a system of periodic measurements part of the general scheme of medical inspection of school children. In this connection it was stated that at Marlborough, where annual measurements have been recorded for twenty years, the average size and weight of the boys has been steadily increasing. From a comparison of these statistics it appears that in 1906 the boys 14 years old were about 5 pounds heavier and nearly 1½ inches taller than those of the same age in 1886. The 16-year-old boys of the present date keep up in proportion, being three-quarters of an inch taller and 8 pounds heavier.

A New Schematic Eye.—For enabling its students to acquire the technique of ophthalmoscopic examinations, the Chicago Eye, Ear, Nose, and Throat College has installed an equipment of schematic eyes. They are built on the model devised by its president, Dr. W. A. Fisher, who has long recognized the need of a means of teaching the use of the ophthalmoscope.

New Hospital for Tuxedo.—Plans have been made for the erection of a $100,000 hospital in Tuxedo under the direction of a committee composed of members of the summer colony.

Professor von Leyden has resigned the Chair of Special Pathology and Therapeutics in the University of Berlin, his retirement to take place at the close of the current semester. Prof. W. His, a son of the famous anatomist and embryologist, has been appointed to succeed him.

Iowa State Homeopathic Journal.—The Iowa State Homeopathic Medical Society has decided to publish a monthly journal under the editorship of Dr. G. A. Huntoon, the secretary of the association.

Chicago School of Sanitary Instruction.—Articles of incorporation have been granted for a school bearing this name, with Health Commissioner W. A. Evans, Assistant Health Commissioner Reilly, and Dr. J. Biehn as founders.

Pennsylvania State Medical Examinations.—Of 367 applicants for license to practise medicine in the State of Pennsylvania, only 39 failed to pass the formal examination. This is the smallest number of failures since the medical examination act has been in force.

State Board of Medical Examiners.—At an adjourned session held in Albany on August 1, the recently appointed State Board of Medical Examiners adopted rules for its guidance in marking the papers of applicants for licenses. The rules are said to involve few changes from those of the old board.

Obituary Notes.—Dr. EDGAR ELTING of Kingston, N. Y., died on July 27, at the age of seventy-nine years. He was descended from a long line of physicians, some of whom served in the Revolutionary Army. In 1884 Dr. Eltinge removed to Brooklyn, where he practised for twenty years. About three years ago he gave up active work on account of failing health and returned to Kingston.

Dr. LUCY HALL-BROWN of Brooklyn died on August 1 at Los Angeles, Cal. She was graduated from the University of Michigan in 1878, and continued her medical work abroad. She is said to have been the first woman entered in the clinics of St. Thomas's Hospital, London. For some years she was superintendent of the Massachusetts Reformatory. In 1887 she began practice in Brooklyn, and became prominent in medical circles.

Dr. WILLIAM T. HOWARD of Baltimore died on July 31 at Narragansett Pier, R. I., at the age of eighty-six years. He had been a resident of Baltimore since 1866, in which year he was appointed adjunct professor of physiology in the University of Maryland. A year later he was made the first incumbent of the new Chair of Diseases of Women and Children. About ten years ago he retired from active work and was made professor emeritus.

Dr. G. R. GWYNNE of Lebanon, Tenn., died suddenly of heart failure on July 23, at the age of sixty-four years. He had lived in Lebanon all his life, and was an active member of the County Medical Association. For years he was city health officer of Lebanon.

Dr. RUDOLPH L. DODGE of Portland, Me., died suddenly while in his automobile on July 28. He was born in Scarsport in 1840, and, after having served as second lieutenant through the Civil War, he entered Bowdoin Medical School, from which he was graduated in 1874. Since this time he had practised in Portland.

Dr. JOHN C. BUDLONG of Providence, R. I., died on July 24 after a long illness. He was born in Cranston in 1836, and was a lineal descendant in the seventh generation of Roger Williams. He was graduated in medicine from the Hahnemann Medical College in Philadelphia in 1863, and served through the latter part of the Civil War as division surgeon. He then began the practice of medicine at Centerdale, removing to Providence in 1868. In 1875 he was made surgeon-general of the State with the rank of brigadier-general, and he had occupied many positions of prominence in homeopathic medical societies. In 1903 he was elected to the Providence City Council, and during the past year was president of the Board of Aldermen.

Dr. J. F. CANAVAN of Traverse City, Mich., died on July 27 after an operation for appendicitis. Dr. Canavan was born in Holyoke, Mass., and received his medical degree from the University of Michigan in 1899. At the time of his death he was assistant superintendent of the Northern Michigan State Hospital.

Correspondence.

SANITARY CONDITIONS AT THE JAMESTOWN EXPOSITION.

To the Editor of the Medical Record:

Sir:—In the issue of the Medical Record for August 3 you raise a question in your editorial as to the healthfulness of Jamestown. I wish to say that typhoid fever is not prevalent and that the sanitary conditions on the grounds of the Jamestown Exposition are excellent. I invite the most rigid investigation and will lend any aid in my power that will tend to make investigation complete. I will be under great obligations if you will publish this letter as prominently as your editorial question.

R. L. Payne, M.D., Medical Director.

THE INCORRECT REPORT OF DR. KNOPF'S REMARKS.

To the Editor of the Medical Record:

Sir:—On May 8, the day following the meeting of the National Association for the Study and Prevention of Tuberculosis, there appeared in the *North American* of Philadelphia a most sensational article, according to which, during the discussion of Dr. Flick's report on medication, I was reported to have advised the killing of dying consumptives quickly and painlessly by heavy doses of morphine and to have admitted that it was my daily practice to do so. It was furthermore said in this article that there had been a bitter debate and that the session adjourned in confusion. These false statements were copied by nearly all the newspapers in the United States, were cabled to Europe, and made the rounds in the papers and magazines of England and the whole European Continent. In spite of explanations and denials I had sent to the Associated Press, in spite of a strong letter written by Dr. George Dock, the presiding officer of the meeting, giving the true version of my remarks, the false statement has continued to be published and republished and commented upon, to the great detriment of the anti-tuberculosis crusade all over the world. For example, ignorant consumptives in St. Louis, who had read the sensational misstatement, refused to receive the nurses sent to them by the Society for the Relief and Prevention of Tuberculosis. The St. Louis *Republic*, which published this news item, said: "Consumptives, since they read that report, apparently have a dread that the visit of the nurse may mean morphine to end their suffering." It became thus necessary to issue a statement by order of the president of the National Association for the Study and Prevention of Tuberculosis, to the effect that no such remark was made by me, and further that: "Quite apart from the false position in which the speaker was placed and the injury done him, the publication of such a piece of sensationalism cannot fail to have a very deleterious effect upon impressionable tuberculosis patients throughout the country and may keep others from seeking needed medical aid."

I had hoped that this would put a stop to all further comments on and circulation of the sensational falsehood. I am free to confess that I have longed for the time when the lie would die out, but it seems that such a lie dies hard. The *Kansas City Journal* recently published an editorial under the heading "Should Doctors Kill?" from which I quote the following: "The question whether a physician is justifiable in shortening the life of a patient suffering from an incurable disease by administering anesthetics was given a fresh impetus recently by the declaration of Dr. S. A. Knopf before the Tuberculosis Congress in Washington, advising that consumptives should be given heavy doses of morphine to hasten the end. To the credit of the profession it must be said that physicians generally repudiate the idea as atrocious and a violation of medical ethics." In Dr. Dock's letter above referred to, as well as in the statement authorized by the president of the Congress, the absolute falsehood of the newspaper report was clearly shown. Equally untrue was the report of the alleged "adjournment in confusion" and the "lively and bitter debate" which followed Dr. Flick's report, condemning the use of morphine and its compounds. In refutation of this reflection made on a body of scientific men, composed of many of the leading physicians, I would cite an extract from a letter which was received recently from Dr. Joseph Walsh, the secretary of the section: "I was present as secretary of the section at which you spoke, and instead of the section breaking up in confusion, as was stated in the newspapers, the section closed in the perfectly regular way, and your statement as generally understood by the medical men seemed to be generally agreed with."

I beg the medical press of the United States to copy this communication, in the hope that it will help individual members of the profession to refute once for all the inconceivable proposition that any physician true to his calling could possibly propound such a doctrine as shortening the life of any patient entrusted to his care. To the individual members of the profession in this country and abroad I address a personal appeal to embrace every opportunity to disabuse any individual who may labor under the misapprehension that I or anybody else of the American medical profession recommended shortening the lives of consumptives or any others by the administration of chloroform, morphine, or similar narcotics. I make this appeal not merely for my own sake, but above all for the sake of truth and for the sake of consumptive sufferers in this and other countries. S. A. Knopf, M.D.

New York, July 30, 1907.

NO DANGER OF TYPHOID FEVER AT JAMESTOWN.

To the Editor of the Medical Record:

Sir:—In reply to an editorial in the Medical Record of August 3, 1907, I am glad to be able to say to those intending to visit the Exposition that there is no danger of contracting typhoid fever. It is entirely safe for any one visiting that place to drink any water on the grounds freely and to eat ice cream or whatever he may wish if purchased on the grounds. The water supply is the same as that of the city of Norfolk proper, and this water comes from a lake well protected and watched to avoid contamination. This water has been recently examined by the United States Government and pronounced excellent in quality. Among the three thousand people employed at the Exposition grounds, fourteen cases of typhoid fever have developed, which is about two-fifths of 1 per cent., and this includes all that have occurred since last fall. Only one of these persons lived on the grounds, thirteen of the fourteen spending more than half of their time away from the grounds.

Because this case was suspected to come from milk contamination, all the milk supply other than condensed milk and that from two dairies has been cut off from the grounds.

All the ice cream allowed in the grounds is prepared by a reliable ice cream company of Norfolk, and the milk they use consists of 40 per cent. cream, which comes to them packed in ice from Cooperstown, N. Y., and is then mixed with milk from dairies in this vicinity. The only dairies supplying this milk are those that show certificates from the health department at Norfolk. Dr. Santee of Washington only last week examined all the dairies here, and only those he pronounced good have certificates. From personal observation I can say that the cans and milk are carefully handled by this company.

In Camp Smith and that of the Twelfth Cavalry stationed at the Exposition they are using the same water that is supplied to the Exposition. There are about thirteen hundred men, and in four months' time only one case of typhoid has occurred, which is little short of marvelous. Even this case did not give the usual blood reaction for typhoid.

At Pine Beach, which is outside the Exposition grounds, pumps have been driven in the ground and cesspools are scattered around, but Dr. Blue of the Public Health Service is trying hard to purify this spot, and twelve offenders have already been fined. The best places at Pine Beach use the Norfolk company water, which is of high quality; it is the cheap places there that are dangerous. The Exposition and county have agreed to put in the pipes to such places and bear half of the expense, so that eventually all of Pine Beach will be safe so far as the water is concerned. Pine Beach has no official connection with the Exposition.

Among the West Point cadets three cases of typhoid fever developed after they had left the Exposition, but it is not fair to say that they were contracted at the Exposition, for these young men went all around and drank water from many sources; they probably also ate raw oysters and took milk in some form. Among the many companies of troops that have been stationed at the Exposition not a single case of typhoid has been reported, and reports have come from them stating that the men remained in the best of condition after their return. Only one case so far can be traced directly to the Jamestown Exposition grounds, and that was probably from contaminated milk.

There are 200 men in the Government employ who live on the grounds and have been there for two months without any cases of sickness among them. If the water

was contaminated some of them would have shown it.

To those visiting the Exposition I would advise that they abstain from raw oysters and from drinking milk and eating ice cream promiscuously outside of the grounds. Norfolk city and Norfolk county water are both safe, but all other should be boiled. Any water on the Exposition grounds is safe. Such a finding reflects credit on those in charge of the sanitary affairs at Jamestown.

JOHN W. WINSTON, M.D.

NORFOLK, VA.

OUR LONDON LETTER.

(From Our Special Correspondent.)

AMALGAMATION OF HOSPITALS AND SOCIETIES—FINAL MEETINGS OF OBSTETRICAL AND GYNECOLOGICAL SOCIETIES—INTERNATIONAL CONGRESS ON SCHOOL HYGIENE—DEATH IN DEEP SEA DIVING—OBITUARY, DR. DUNSMURE.

LONDON, July 19, 1907.

AMALGAMATION of hospitals and societies is still exciting some discussion. With regard to the former you are aware that the union of the orthopedic hospitals has been successfully carried out, largely by the assistance of King Edward's Hospital Fund. Another effort of the kind is being made. On Tuesday a meeting was held of the supporters of the Hampstead Hospital to consider a proposal made at the instigation of the King's fund to amalgamate with the Northwest London Hospital. An outline of a scheme was submitted by the council, and after some discussion a committee was appointed to consider the proposal and report. It is probable that in time the amalgamation will be carried out, for the influence of the King's Fund is far-reaching and the plan seems reasonable.

As to our societies, most of them have become merged in the Royal Society of Medicine, and in some cases the full consequences do not appear to have been foreseen, so that here and there little clouds are already visible. One is connected with the new section which absorbs the two societies devoted to obstetrics and gynecology. The list of officers recommended for the new section shows such a preponderance of the obstetrical fellows that it recalls the jealousy with which the birth of the younger sister was regarded and excites in some quarters surprised comments. But perhaps too much importance has been attached to this. At any rate the junior society—the gynecological—is not, as a body, dissatisfied, for at its concluding meeting as an independent institution a resolution was passed seconding its "appreciation of the courtesy and cordiality with which the Obstetrical Society of London united with our society in their arrangements for amalgamation."

I will turn, therefore, to the practical work of these societies at their concluding meetings. That of the obstetrical was held on the 3d inst., when Dr. F. E. Taylor described a case in which suppuration of an ovarian cyst seems to have been caused by the typhoid bacillus. The patient had suffered from the fever in April, last year, and a movable abdominal tumor was discovered during her convalescence. This gradually increased in size and at length operation seemed advisable. The abdomen was opened and the tumor found to be an inflamed cyst of the left ovary with some adhesions to omentum. It was removed entire and recovery was ideal. It was unilocular, about the size of a man's head, held 2½ pints of yellow pus, free from odor, and from the pus a pure culture of *Bacillus typhosus* was obtained. Dr. Taylor thought the infection reached the cyst by way of the blood and showed the pyogenetic properties of the bacillus.

The president, Dr. Spencer, was surprised to hear that the bacillus could survive in ovarian fluid for twelve months. He asked whether Widal's reaction was considered proof positive of typhoid fever, as a few years ago some physicians did not so regard it. To this Dr. Taylor replied that much depended on the technique of its performance, especially as to the dilution and time limit.

A skeleton of an extrauterine fetus from a woman without any history to suggest it was shown by Miss Adrich-Blake; two specimens of fibroid associated with bleeding after the menopause by Dr. Lewers; and a calcified fibroid enucleated for bleeding fifteen years after oophorectomy by the President.

At the gynecological's final meeting on the 11th inst. Dr. J. H. Swanton showed a fibroma removed from the vagina of a widow of forty. It was pedunculated and measured three fourths by one third inch. Dr. Macnaughton-Jones said it was important to know if these rare tumors degenerated. He thought some were sarcomatous. Prof. J. W. Taylor had met with four such growths and one of them recurred three times, though histologically it was only a simple myoma. Dr. Swanton further showed a cystic adenocarcinoma of the ovaries and appendix vermiformis from a patient of sixty-nine. It had originated in cystic growths. The President, Mr. W. D. Spanton, remarked that growths arising in this way often proved extremely malignant. Dr. Giles thought carcinoma of the ovary, if free fluid were absent, was often not directly diagnosed. Dr. Macnaughton-Jones showed a large myoma, encapsuled in peritoneum, which arose from the uterine body and cervix, from a patient of thirty-two, unmarried, troubled with menorrhagia and anemia. Both ovaries were removed, as they were cystic and had degenerated. Dr. Swanton showed a cyst of the clitoris from a patient of twenty. It contained blood, pus, and sebaceous matter, and was supposed to have been caused by a blow. It had been growing about three months.

The President then delivered a valedictory address in which he summarized some of the good work of the society during its twenty years' existence. He recalled that the first specimen shown was a multiple myoma and a criticism then made was still applicable, *viz.*, to extirpate a tumor which gave little or no trouble, simply because it was a tumor, was a proceeding a surgeon ought to decline.

The second International Congress on School Hygiene is to be held in London next month and the King has given it his patronage. But great dissatisfaction is felt with the way the Board of Education has failed to do anything to promote the success of an undertaking favored by His Majesty. That board has been asked by the Executive Committee to do three things. It has not done one of them. (1) It was invited to send delegates; it nominated three officers "to attend the meetings and report" for the purposes of the board, but they were not to be known as "delegates." (2) It was asked to hold a reception in conjunction with the Foreign Office for seventy-five foreign delegates, but had not the courtesy to reply, and when questioned in the House of Commons Mr. McKenna said, on the 15th inst., the board did not think it advisable. The board, one may suppose, does not think courtesy should be taught by example, whatever its teachers may do by precept. (3) The board was asked to approach the Foreign Office so that invitations might be sent through the diplomatic channels in accordance with custom, as otherwise some countries would be unwilling to appoint delegates. This was known to be the case with Germany and France, the former being the originator of the Congress and the latter having done everything possible to promote its success. The board also refused this request, not openly, however, but in a "private and confidential" letter to the chairman of the Executive Committee. There are other causes of discontent and even indignation among those interested, but these three seem quite enough to justify the dissatisfaction which is expressed in all directions.

At an inquest on a diver who lost his life through the entanglement of his lines while he was engaged in deep water investigating the wreck of a torpedo boat some remarkable evidence was given as to the management, but the jury found that no blame was attachable to the officers engaged, and commended the bravery of a fellow diver who had, at great risk to himself, endeavored to save the victim of the accident.

Staff Surgeon Oswald Rees, Secretary to the Admiralty Deep Sea Diving Committee, explained that it was necessary to allow time equal to that spent in the water for the ascent. The usual time to stay at the sea bottom at the depth of twenty-five fathoms was twenty minutes. By that time the blood would be saturated with air and the tissues partly so, and if the diver were raised suddenly bubbles would penetrate to the heart, causing sudden death. At the post mortem in this case, at which Prof. Haldane of Oxford assisted, three bubbles of nitrogen were found in the heart. When the diver was got on board he was suffering terribly from shock and stone deaf. No diver had ever recovered after so long an immersion at such a depth.

Dr. James Dunsmure, Ex-President of the Royal College of Surgeons of Edinburgh, died suddenly on the 15th inst. He had held the surgeoncy to a number of the Edinburgh charities, including the Royal Hospital for Children, the Maternity Hospital. He was a Fellow of the Med.-Chir., and the Obstetrical and Harveian Societies of Edinburgh. His early education was in Edinburgh, where he graduated after spending some time in Berlin, Vienna, and Prague. His M.B. was 1867, in which year he took the college license. He became M.D. and F.R.C.S. in 1870-1, from which time he steadily rose to the highest collegiate honors. In 1901 the University of Glasgow conferred on him the LL.D.

Progress of Medical Science.

Boston Medical and Surgical Journal, July 25, 1907.

Hydrophobia and Its Prevention.—C. P. Sylvester goes into a description of hydrophobia and believes that the occurrence of cases of this disease in this country is a reflection upon our ability in the department of sanitary science. It is a duty incumbent upon us to furnish the laymen with such knowledge that they may assist us in obtaining proper laws for its eradication, and it is upon us that the duty devolves of actively guiding into existence such national and State laws as the following: (1) Control of the disease in the United States to be placed under the supervision of the Chief of the Bureau of Animal Industry at Washington, as are other epizootic diseases, such as foot-and-mouth disease, according to the Act of Congress of May 29, 1884. (2) Full authority vested in the State cattle and other appointed commission to act as may be necessary for the eradication of the disease, in conjunction with the United States Bureau of Animal Industry at Washington, whenever rabies appears in the State. (3) All licensed dogs to wear collars and metal plate of special form, that they may be readily recognized. (4) Prompt capture of all dogs not properly tagged, with subsequent humane destruction, unless properly licensed within a short time. (5) Efficient muzzling of all dogs unrestrained in public places for a period of at least one year. (6) Dogs imported from countries other than those from which rabies is excluded to be quarantined for six months.

The Contamination of the Air of Our Cities with Sulphur Dioxide the Cause of Respiratory Disease.—Theodore W. Schaefer has been studying the noxious effects of sulphur dioxide as an impurity of the atmosphere for the past ten years and has arrived at the conclusion that it is one of the most potent causal factors of asthma. Writers on hygiene and sanitation have paid but little attention to the subject of air vitiation by sulphur dioxide gas. The weight of evidence concerning the relation of this gas to public health indicates that its effects are really serious if not lasting on certain susceptible persons, and that its presence in atmospheric air is a positive menace to the hygienic welfare of living beings.

New York Medical Journal, July 27, 1907.

Operations for Cleft Palate and Their Results; Especially in Respect to the Improvement of Speech.—The conclusions that G. Hudson-Makuen comes to are that an operation for the closure of a cleft palate should be done only when there is a fair likelihood of success; it should be done only by those possessing special skill in naso-pharyngeal and oral surgery; when it is probable that several operations may be necessary the parents or patient should be so informed; the operation should be done as early as possible; in the difficult adolescent cases the operation after a preliminary tracheotomy may be preferable; there are two reasons for attempting to close a cleft palate, namely, to improve the general health of the patient, and to increase the efficiency of the faculty of speech; the general health of the patient is benefited in two ways, namely, by improving the hygiene of the nasopharynx and the oral cavity and by improving the general morale of the patient; the speech is improved by a course of psychophysical training in which the patient is taught first to recognize normal speech and then to make the best use of his still imperfect organs in its production.

Phagocytosis, Etc., in Sputum, as a Measure of Resistance in Tuberculosis.—Albert H. Allen concludes that (1) 59 per cent. of the cases show phagocytosis when their phagocytic index was applied. Eighty-two per cent. of the cases show phagocytosis when all cases showing phagocytosis at any time were included. (2) Phagocytosis in ordinary sputum examination seems of little practical value in prognosis. In large groups of cases certain features may be observed: e.g. phagocytosis was much less in his tuberculin cases. (3) From three autopsies and from the variation observed, whether of sputum taken at intervals of minutes or months, it would seem that a specimen from the homogenized daily output is necessary for much accuracy. (4) Tuberculin reactions failed to produce positive and negative phases. (5) Phagocytosis seemed not to vary with the presence of bad symptoms. (6) Phagocytosis in sputum deserves a more extended study, especially since the rôle of phagocytosis in general is still undetermined. (7) Disintegrated tubercle bacilli, parallels, variation in staining, all seem to be of no practical use in prognosis. This is in harmony with the literature.

Consanguinity: A Factor in Immunity to Scarlet Fever.—Julian Walter Brandeis has become impressed with the fact that with scarlet fever occurring in uniformly large families it was the rule to have no secondary cases develop. This evidence of low degree of scarlet contagion differed so markedly from the estimates placed by various authors of the contagiousness of the disease in relation to children in general that he decided to tabulate a certain number of cases. The table shows that, omitting the children who had scarlet fever previously, thirty-nine children were exposed in twenty-five families. Four secondary cases developed. This means that the percentage of contagiousness of scarlet fever among members of the same family, as derived from the original cases, reaches only the low figure of 10 per cent. In contrast to this Holt says that about 50 per cent. of all children exposed to scarlet fever are attacked with the disease; Koplik states the same figure; and Carr places it as high as 56 per cent.

Journal of the American Medical Association, August 3, 1907.

Intramuscular Mercurial Injections in Syphilis.—W. S. Gottheil recommends as a routine treatment in syphilis the intramuscular injection of insoluble mercurials, claiming for it over other methods of administering mercury a greater rapidity of action, especially in acute cases, more security against relapses, and lessened danger of hereditary transmission of the disease. The patients themselves soon come to prefer the treatment; it is much less trouble to receive an injection at the doctor's office once in ten or fourteen days than to be taking pills or medicine several times a day. It is a lesser tax on their memory and time, and the risk of publicity is less. The injections, properly administered in the gluteal region, cause very little pain and very slight inconvenience, indurations are exceptional and do no harm; they are indications, other things being equal, for reducing the frequency for the amount of the injections. On this account he sometimes prefers to give a five or six-drop injection weekly instead of twice that amount once in two weeks. Abscesses, he declares, are due to faulty technic, and he has found them, even in hospital and dispensary work by internes and assistants, very rare indeed. The danger of pulmonary embolism after the injections is considered by Gottheil almost illusory. He always insists on the precaution of disconnecting the syringe and watching the lumen for a few seconds before making the injection, and with this it is difficult to see how it could occur. There is evidence of the entrance of the point of the needle into a vein in about one in twenty-five injections, but this simply entails its withdrawal and reinsertion elsewhere. Mercurial intoxication may occur, but is less frequent than with the use of mercury in other ways. He always begins with a small dose and progresses up to a full one as the patient's reaction is learned, and it is safe to do so. Having the treatment directly under the control of the physician is a great advantage of the method over other modes of the administration of mercurials.

Liquid Air in Dermatology.—H. H. Whitehouse believes that we have in liquid air a dermatological remedy of real worth, at least in a limited field. He gives its physical properties and the facts so far as known as to its bactericidal value, which seems to be practically *nil*. We must look, therefore, to changes induced by it in cellular metabolism for its therapeutic changes induced by it in cellular metabolism for its therapeutic effects, and he states that it relieves pain in pathological conditions, lessens discharge and odor and tendency to hemorrhage. Mild applications favor healthy granulation, while stronger ones, he declares, destroy exuberant growth. It has little reactionary effect on scar tissue, and, therefore, he believes that it has a diagnostic value in epithelioma. The conditions in which he finds it of value are pigmentary, hairy, and vascular nevi, angiomata, lymphangioma circumscriptum, lupus erythematosus, lupus vulgaris, and epitheliomata (unaccompanied by lymph-gland invasion). The technic of its use is described. It should be applied on a swab which can be adapted to any form desired, and the elements governing the effects produced are: 1, the degree of saturation of the swab; 2, the accuracy of contact; 3, the amount of pressure exerted, and 4, the duration of the exposure. On a thorough appreciation of these, coupled with correct judgment as to the in-

terval between exposures, success and failure depend. As a rule, the slower the method the better the result. Special directions are given as to the treatment of the various conditions and a number of cases are reported. He thinks that in a certain class of epitheliomata it is a distinct power for good.

Fatal Hemolysis After Transfusion.—W. Pepper and V. Nisbet give the history of a rather puzzling case of hemorrhagic diseases in which direct arteriovenous transfusion was performed on two separate occasions. On the first occasion the blood (wife's) was allowed to transfuse for a little more than an hour and a half, and the patient, who had apparently been rapidly sinking, showed marked improvement. There was a slight suggestion of hemolysis in discoloration and urobilin in the urine, but this had nearly disappeared when the second arteriovenous anastomosis was made with another person (brother-in-law) two days later. After the second transfusion the condition changed rapidly for the worse, there was marked evidence of hemolysis, bloody urine, jaundice, high temperature, etc., the patient failed rapidly and died within five days. The impression is given that possibly the first transfusion may in some manner have caused the formation of hemolytic bodies that, after the second transfusion, found abundance of vulnerable corpuscles on which to work. The authors do not venture any positive opinion, however, as to the rôle of the second transfusion.

Hemiplegia as a Complication of Typhoid Fever.—A case of this rare complication of typhoid is reported by F. Smithies, who reviews the literature of the subject, and tabulates and analyzes the cases reported. In his patient, the gradual onset of the paralysis and its progressive recovery pointed to a thrombotic rather than an embolic or hemorrhagic lesion, and other facts like the absence of cardiac lesion, the large involvement of cortical motor centers and a leutic history also support this view. Statistics, so far as available, show that the complication is most common in males and in young adults, in only two cases the age given being over thirty. In few instances were there other lesions than those connected with the fever reported. Aphasia was a common symptom. In only one case was it reported as occurring during the first week of the fever; eight instances are recorded as occurring during the second week, eight in the third, two in the fourth, and in the remainder there was more or less permanent impairment, inability to perform the more delicate movements, atrophies, contractures, permanent aphasia, or speech impairment, etc. The mentality seems less affected, but in some cases there seems to be a greater than ordinary tendency to the post-typhoid psychic neuroses. When occurring early in the fever the cause is likely to be an embolus or slight hemorrhage; if later, thrombosis is probable. The treatment is described in some detail, the measures recommended are largely those used in hemiplegic attacks generally, modified of course by the contingencies of the existing disease.

Blood Injections in Pseudoarthrosis and Delayed Callus Formation.—V. Schmieden calls attention to Bier's method of treating pseudoarthrosis and retarded callus formation by injections of human venous blood between the separated fragments of bone. It is based on the theory that the formation of callus in fractures is due to the inflammatory reaction caused by the hemorrhage attending the fracture, and this inflammatory reaction failing, we can re-excite it by making, so to speak, an artificial hemorrhage. In Bier's clinic, the technic is as follows: The site of the "false joint" as well as the arm from which the blood is taken are rendered aseptic. By the use of a light constricting band the veins are made prominent and then one of the largest vessels is punctured or incised and 30 or 40 c.c. of blood are drawn into the syringe. The syringe must be large and its needle sufficiently strong in order that the blood can be readily forced through it. It must be strong also because much force is needed to inject into the hard scar tissue. The blood must be forced, not only between the fractured ends, but also around them in places where, from periosteal and paraosteal tissue, callus may be formed. It is important also that the blood be injected immediately after its removal, using the same syringe into which it has been drawn, as it tends to prevent coagulation in the syringe. Blood containing its fibrin gives better results than defibrinated blood. From 20 to 40 c.c., according to the size of the bones, is injected, the operation being repeated every ten days. In most cases there is a visible reaction and after its subsidence a tumor remains that becomes callus. Sometimes one or two injections suffice, in other cases five or six may be needed. The more recent the fracture the greater the success, hence the best results are obtained in cases of retarded callus formation. In some old cases of pseudoarthrosis the method fails, but the same is true of all other methods. In a large number of injections made in this way he has never seen any harmful effects. He has often injected blood taken from another healthy subject and has found it more effective. The facts support the conclusion that the extravasation of blood is the natural irritant which excites callus formation. The technic is simple and harmless, and the method is recommended with the hope that the results obtained in Bier's clinic will be substantiated by the experience of others.

Slow Fever.—H. F. Harris describes a type of fever met in the swampy regions of Southern Georgia. He defines it as "a continued fever occurring almost exclusively during the warm months and lasting from one to ten weeks," and gives the following synonyms: Typho-malarial fever; simple continued fever; remittent malaria fever; Willacoochee fever; continued fever; bilious fever; typhoid fever. In regard to the etiology he states that typhoid and paratyphoid bacilli were demonstrated in 73.3 per cent. of all cases investigated; of these the typhoid organism was found in 51.1 per cent., the paratyphoid in 20 per cent., and a mixed infection in 2.2 per cent. of the cases. He discusses the various methods of differentiation of the bacilli. He summarizes the histories of several cases and gives the blood findings: "Stained preparations of the blood by the Romanowski method were made in every instance, and not in a single case was the malarial parasite found. In 18 instances the hemoglobin was estimated; the figures ranged from 60 to 100 per cent.; the amount of hemoglobin was not entirely dependent on the stage of the disease, as it was found to be very low in several cases during the first week of the disease. In only 1 case were the leukocytes counted, the number being 7,800 to the cubic millimeter. The average of differential counts in 11 cases is as follows: Small lymphocytes, 17.7 per cent.; large lymphocytes, 9.4 per cent.; polymorphonuclear, 71.6 per cent.; eosinophiles, 1.3 per cent. Agglutination tests were positive in only 12 cases. The prognosis in this disease, he says, is generally conceded to be better than in typhoid, and he believes that there can be no reasonable doubt that this assumption is correct. The fact, in a large measure, furnishes the basis for the commonly-expressed opinion among Southern physicians that "slow fever" is a distinct and separate disease. The mortality in his series of cases is certainly lower than is usually observed in typhoid fever, but, of course, from such a small number of instances of the disease no general conclusions could be drawn. He states that he has had no great experience in the treatment of this disease, but thinks that everything warrants the opinion that it should be treated like typhoid. Many physicians employ large doses of quinine throughout the course of the disease, with the belief that its course is thereby shortened.

The Lancet, July 20, 1907.

A Common Sporadic Seven-Day Fever of Indian Ports Stimulating Dengue.—Leonard Rogers fully describes this seven-day fever, which is common, with a definite seasonal distribution, in the large seaports of India. It is rarely seen far from the coast line. It resembles dengue in its sudden onset, the severe headache and pains, the character of the tongue, the rash, when present, and, to some extent, in the seasonal incidence and its distribution. The main points of difference are shown as follows: Dengue is prevalent at long intervals in epidemic form, attacking large proportion of residents; seven-day fever is prevalent annually in sporadic form. Dengue specially attacks coast towns, but spreads far inland; seven-day fever is only known near the coast, so far. Dengue attacks Europeans and natives equally, whereas the fever is very common among Europeans, but comparatively rare in natives. Dengue occurs mostly in the hot months, but may prevail in the cold season; the fever prevails in hot and rainy seasons only. In dengue relapses are very common in the same year as first attack; in the fever relapses are rare and are not in the same year as first attack. Pain is very severe in dengue and breakbone in character; in the fever the pain is moderately severe, as in influenza, and not of breakbone character. In dengue the joint symptoms are very common and characteristic; in the fever they are absent or only present as slight pain. The convalescence in dengue is very tedious, lasting from one to three months, with persistent joint pains; in the fever it

is rapid and with no after joint pains. In dengue the fever lasts two or three days, falling to normal with crisis; occasionally there is a very short secondary rise; it is markedly remittent; in the fever the fever lasts eight or more days, with typical saddleback remissions to 100° or 99° F. only; otherwise it is continued in type. In dengue the pulse is rapid; in the fever it is slow, especially in the terminal rise.

Experiments on Prolonged Protein Feeding.—David Forsyth writes on this subject with special reference to the thyroid gland and the osseous system, and concludes that fowls kept for long periods on a protein diet, but otherwise under healthy conditions, show no hypertrophy or microscopic changes in the thyroid glands; that their bony tissues are not affected provided the deficiency of calcium and other bases in the meat diet is made up by a supply of lime; in none of the birds was any change indicative of gout observed; each of the four fowls maintained under the above conditions showed an unusual amount of colloid in their pituitary glands; that the thyroid glands of carnivorous birds of prey are not obviously larger, proportionately, than those of other classes of birds, nor are there any peculiarities of microscopic structure in the glands of carnivorous and graminivorous birds referable to differences in their natural foods.

Male Triplets with Eclampsia in a Patient Aged Sixteen Years.—Robert Ollerenshaw reports this case, which was noteworthy because of the condition of male triplets, the complication of eclampsia, and the youth of the mother and father (the age of the latter being seventeen). The respective weights are as follows: The first, 2 pounds 14 ounces; the second, 2 pounds 6 ounces; and the third, 3 pounds 2 ounces. The third child, the heaviest, was nourished from a separate placenta, and was the result of the fertilization of one ovum; the first and second fetuses were uniovular, having a common chorion, the individual amniotic sacs having been broken through probably by fetal movement. The two placentæ were united by their edges so as to form one large placenta, which was expelled quite intact with the membranes five minutes after the birth of the third child.

Injury to Shoulder; Herpes Zoster; Influenza.—John Allen reports the case of an eighteen-year-old youth who received an injury to the back of his left shoulder. On examination no brusing was seen and no fracture or dislocation could be discovered. Four days later an herpetic eruption appeared on the posterior aspect of the left side of the chest and the left arm and forearm. This was accompanied by a great deal of pain. He progressed favorably for the next five days. Then there occurred an attack of influenza with a scarlatiniform rash over his body, most marked in the lumbar region and the buttocks. The rash disappeared in forty-eight hours and there followed no desquamation. In this case it was somewhat difficult to decide whether the initial pain complained of resulted from the injury or whether it merely heralded the onset of the herpes zoster, the injury either precipitating the onset of the herpes, or drawing the patient's attention to the pain. The attack of influenza was interesting because it was accompanied by a rash, a rather uncommon though not unknown occurrence.

British Medical Journal, July 20, 1907.

Laryngismus Stridulus in Infants.—Eustace Smith has met with a number of cases of laryngismus stridulus attacking healthy young infants within the first month of life; without exception there was one common feature, namely, extreme nasal obstruction due to adenoid overgrowth and post-nasal catarrh. In many cases the spasmodic movement is not confined to the larynx, but involves the gullet as well. In newborn infants, as in older children, the degree of laryngeal distress varies widely from an occasional crow or croak in mild cases to a severe and prolonged spasm in which breathing completely ceases, the face grows slate-colored, and the infant seems at the very point of suffocation. The attack has generally come on silently. The treatment consists in removing the cause, which, he believes, is to be found in the nasopharynx. In mild cases a few drops of resorcin solution, one or two grains to the ounce of normal saline, instilled into the nostrils several times a day, will soon put a stop to the crowing. But in bad cases the nasopharynx must be scraped before applying local remedies. The operation should be performed early. If a child is seen during a seizure, the tongue should be hooked forwards by a finger passed into the throat or grasped with the tongue forceps and traction made so as to excite a return of respiration. Little shocks are useful. If respiration is not restored, artificial respiration should be resorted to and persevered with. Insufflation was successful in an obstinate case of arrested breathing from anesthesia.

Remarks on the Value of Rhythmical Exercises in the Treatment of Spasmodic Neuroses.—T. Stacey Wilson says that in all our dealings with the nervous system we cannot afford to forget the important rôle played by *habit*. What we call habit is based upon the physiological law that the more a nerve path is used the more easily does it transmit nerve impulses, or the more any particular nerve mechanism is used, within the limits of its power of nutrition, the more easily does it work in the future. His paper deals with some ways in which recognition of this law may aid in dealing with disordered functions of the nervous system.

Iodine and Typhoid Fever.—George V. Perez's results with the internal administration of iodine in the treatment of typhoid fever have been so striking that he tells of his experience with it. If administered in the beginning it acts almost like a specific, shortening the duration of the illness, which in some cases would appear to abort, and modifying favorably most of the symptoms. He uses it in the form of the B.P. tincture, 3 to 15 minims diluted in 1 to 2 drachms of rum or cognac in about 1 to 2 ounces of water, with a little sugar. This is administered three or four times a day.

A Fifteen-Pint Hydrocele.—A. E. Horn reports an interesting case of a man, aged thirty, with his scrotum enormously enlarged and hanging down to his knees. The swelling proved to be a small double inguinal hernia and a left hydrocele. The hydrocele was tapped and a measured quantity of fifteen pints of fluid removed, in addition to about half a pint which was unavoidably lost. The fluid was yellow, specific gravity 1020, cloudy from cholesterin plates, with a few leucocytes, alkaline in reaction, and was almost solid with albumin on boiling. No spermatozoa were to be found. He thinks that this quantity of fluid in a single hydrocele must be almost a record.

Berliner klinische Wochenschrift, July 15, 1907.

Hyperostosis of the Superior Maxilla.—Walliczek, in discussing this condition, of which only a few cases have been reported, says that it consists of a proliferation of the bone of the upper jaw, which is nearly always symmetrical and usually leads to extreme body stenosis of the nasal passages and consequent interference with nasal respiration. More or less facial deformity is caused through the broadening of the root of the nose and infraorbital swelling, and the maxillary antra are obliterated or greatly diminished in size. The condition in most cases is the result of trauma, but it is not yet certain whether other factors such as dental caries, syphilis, tuberculosis, acute infectious diseases, etc., may not also induce it. In the author's case multiple caries of the teeth seemed to be the sole cause of the disease. The prognosis is unfavorable and it is advisable first to resort to internal and expectant treatment. An energetic course of mercurial or mixed treatment should always be employed before attempting any operative interference. Surgical measures should be restricted to the removal of the deformities and to the clearing out of the nasal passages. The author's patient was a man of twenty-seven, who six years previously had noticed the beginning of the malady as a bony swelling starting below the right eye close to the nose. This gradually increased, the condition became bilateral, and finally he grew unable to breathe at all through the left nostril and very little air could pass through the right. The result of operative treatment was not particularly satisfactory and the author states that in another case he would first resort to antisyphilitic treatment, even though, as in the present instance, there appeared to be no reason for supposing that syphilis was concerned in the causation of the condition.

Münchener medizinische Wochenschrift, July 9, 1907.

The Bier Treatment of Seasickness.—Schlaeger, in speaking of this subject, says that the vascular system may be likened to a system of communicating tubes of varying size and with elastic walls of different degrees of resistance, with an interpolated pump whose action depends on the elasticity of the tube walls. Oscillations of such a system result in fluctuations in the distribution of contained fluid, and therefore congestion and anemia of the capillaries will be produced. On an actively

tossing boat these variations in the distension of the cerebral capillaries may reinforce the heart's action or may oppose it. It is not the anæmia or the congestion that gives rise to the manifestations of seasickness, but the irregular fluctuation in the fullness of the cerebral capillaries. In this way a state of irritation of the cerebral centers is induced and this causes the phenomena of the condition. The author has found that the application to the neck of Bier's congestion bandage is of much service in alleviating, if not entirely preventing, the symptoms of seasickness through the marked dilatation of the cerebral vessels that it effects, and he recommends further trial of the procedure.

Thiosinamin Treatment of Dupuytren's Contraction.—Langemak says that while the thiosinamin treatment of this affection has been found to be one of the most satisfactory as far as end results go, it is open to serious objection on account of the pain accompanying and following the injections and the tediousness of the procedure, since many months often elapse before a satisfactory result is obtained. He suggests a modification, which he has found of much service in seven cases. It consists in making a single injection and then, after the scar tissue has been softened by treatment in the hot air apparatus, breaking up the scar tissue by frequently repeated forcible hyperextension of the affected parts. It is advisable to make the first injection and the first brisement forcé under primary ether anesthesia. Frequently a single application of each is sufficient to correct the deformity, but in others a second injection and numerous extension treatments may be required. It is well to begin with 10 per cent. solutions and not to exceed a 20 per cent. solution. One c.c. of the 10 per cent. aqueous solution is always sufficient for a single injection. In making the injection care should be taken to have the point of the needle sufficiently deep, as otherwise necrosis of the skin may be caused. It is also advisable to see that the urine is free from sugar. On discharge the patient should be instructed to soak the hands frequently in hot soapsuds and to carry out hyperextension.

Deutsche medizinische Wochenschrift, July 4 and 11, 1907.

Vesicular Skin Eruptions in Affections of the Central Nervous System.—Schlesinger says that, leaving out of account the lesions of herpes zoster, the vesicular eruptions accompanying cerebrospinal affections occur in the following forms: 1. Unilateral vesicles on the side of cerebral palsies. 2. The scanty, sometimes bilateral, localized vesicular eruptions in spinal disease, which are most often seen on the hands and forearms. In addition, a third group may be formed of those cases of localized vesicular eruptions in cases of peripheral nerve lesions, and the localized eruptions in affections of the spinal ganglia. Eruptions accompanying affections of the central nervous system may be distinguished from those of pemphigus by the absence of any tendency to become general and by their tendency to develop in certain portions of the body, such as the upper extremities, the trunk, and the back. They are often unilateral and the scalp is usually free. The eruption frequently appears in situations where there are disturbances of sensation. There are often other skin changes in the places where the vesicles occur that may be referred to nervous disease. Affections of the internal organs that might be referred to the skin lesions are absent, while motor disturbances are the rule. The prognosis of the eruption is good and the cutaneous lesion usually heals, with or without scar formation. The number of vesicles is ordinarily small. In pemphigus the reverse conditions are the rule.

A New Blood Test.—Max Einhorn has found that a satisfactory simplification of the benzidin test for blood in the stomach contents, urine, and feces may be made by saturating filter paper with a saturated solution of benzidin in glacial acetic acid and drying it. The paper must not be handled with the bare fingers, as perspiration may give rise to a similar reaction to blood, and an ivory tipped forceps is best used for its manipulation. To carry out a test a piece of the paper is dipped in the fluid under examination and a few drops of peroxide of hydrogen solution are allowed to fall upon the moist surface. The paper is laid on a white, clean porcelain plate and the appearance of a blue color is watched for. In order to avoid error it is wise to set one minute as the limit of time for the appearance of the color for a positive test. Numerous control observations of various sorts have convinced the author of the reliability of the method and he recommends it as a valuable orienting test. If the reaction appears promptly and strongly, or if it remains absent, the result may be accepted; but if there is only a trace of reaction after the expiration of a minute, an ether extract should be made and tested with aloin or the benzidin paper.

Threshold Percussion of the Heart.—Goldscheider recommends a very gentle form of percussion, to which he applies the term threshold percussion, and which is intended to render manifest slight changes which appear at the very threshold of perception. It is particularly well adapted to bring out the relative cardiac dullness and is best carried out by using a small glass rod as a plessimeter. This is provided with a rubber cap (the bulb of a medicine dropper) at the end in contact with the body. It is applied diagonally to the surface and is percussed with the finger at some distance from the rubber-tipped end. Its long axis is kept parallel to the boundary to be determined and is preferably applied over the intercostal spaces. It presents the advantages that through the very small area percussed distinct and sharp localization is possible, that the sound produced may be reduced in intensity by percussing further from the end, that the rod is easier to apply to the intercostal spaces than the finger, and that the direction of the percutory waves is under better control.

The Treatment of Rupture of the Quadriceps Femoris.—Karewski says that modern teaching is strongly in favor of operation in cases of this injury, the usually recommended course of procedure being incision and suture of the several muscle stumps. He, however, does not agree with this, but believes that in most cases it is wiser to act conservatively and to resort to the open operation only when less radical measures have been tried and found ineffectual. The dressing he applies consists of three pairs of adhesive plaster straps, which are split into two tails at the ends applied to the skin. These are placed in position over the severed stumps, with an interval between their free extremities which is bridged over by loops of india rubber cord passed through holes in the plaster. By tightening these cords any desired degree of traction may be exercised on the divided muscle and the ends be gradually brought into approximation. He describes an instance in which this method was successfully carried out. The patient was a man of sixty-seven years, who ruptured the rectus and both vasti through a fall on a stairway. The author intended to do an open operation, but so many complications, such as albuminuria, acetonuria, cardiac weakness, hypostatic pneumonia, etc., developed that radical measures were out of the question. Under the form of dressing indicated above the patient obtained practically perfect function within eight weeks, although owing to local skin lesions it became impossible to resort to massage or other manipulations of the knee.

French and Italian Journals.

Pyloric Stenosis in the Nursing Child.—A. Weymeersch says that congenital pyloric stenosis may first show symptoms in adolescence or adult life. When appearing in the nursling they begin with incoercible vomiting, without bile, occurring soon after nursing, with visible peristalsia, but without appearance of a tumor. Obstinate constipation soon comes on. There are three theories as to the causation of this condition. These are simple spasm, excess of function resulting in muscular hypertrophy, and stenosis from thickened muscle, and true hypertrophy causing stenosis. The treatment consists of arranging the diet so as to produce little residue and little need of function, lavage of the stomach, hot applications over the stomach, sedatives, rectal feeding, and saline infusion for dehydration. The author treated successfully one case, while another died.—*Bulletin de la Société Belge de Gynécologie et d'Obstétrique*, Vol. XVII., No. 4.

Prophylaxis of Infantile Enteritis.—Paul Londe says that superalimentation is the principal cause of infantile enteritis, as well as of most of the nonspecific troubles of infancy, such as bronchitis and pneumonia. The infant should be fed in quantities proportioned to its state of development and digestive secretion, rather than to its weight. It is much better to underfeed than to overfeed. Mothers, and physicians as well, give the infant more food than its digestive organs can take care of, and thus the bowels are disordered, the stools become loose, fetid, of bad consistency, and colic ensues. If the food is not reduced in quantity a serious enteritis supervenes. The efforts of the physician should be directed rather to retarding the increase of weight than to accelerating it. The mother or nurse should always be given a quantity of food that she may not exceed, and should never be allowed to increase the ration except under orders from the physician. When a severe enteritis has occurred the infant must go at once upon water diet, and milk must not be allowed until the bowels have been well emptied. Then it should be added very gradually. Milk is the only proper food until the child is two years of age, when gruels, soups, and eggs may be given cautiously. In some cases of severe enteritis the mother's milk is the only remedy that can be of use, and it must be obtained at all hazards.—*La Presse Médicale*, March 23, 1907.

Book Reviews.

Polypus of the Nose. By Eugene S. Yonge, M.D., Honorary Assistant Physician, Manchester Hospital for Consumption and Diseases of the Throat. London and Manchester: Sherratt & Hughes, 1906.

The author's aim has been to elaborate the theory of causation of nasal polyps which he advanced a few years ago, to present a full account of the general subject of nasal polyps, and to discuss methods of treatment, especially those which aim at the radical cure of the disease. He regards polyps in the nose as edematous hypertrophies of the nasal mucosa, the indirect result of certain mechanical changes in the glands. These changes are distention and cystic dilatation. By certain experiments on cats he has been able to produce localized edema and polypoid outgrowths in these animals. But just why these changes occur in certain individuals, and not in others, we have no means of knowing.

Manual of Operative Surgery. By John Fairbairn Binnie, A.M., C.M. (Aberdeen), Professor of Surgery, Kansas State University, Kansas City; Fellow of the American Surgical Association; Membre de la Société Internationale de Chirurgie. Third Edition, Revised and Enlarged. With 678 Illustrations, a number of which are printed in colors. Philadelphia: P. Blakiston's Son & Co., 1907.

In order to keep this book up to date the author has revised it and enlarged it by about one hundred pages; over one hundred new illustrations have also been added. Among the new material is a description of a few classical operations on the genitourinary organs and on the anus. It must be remembered that this volume is not a complete textbook on surgery. It omits all those procedures which are generally described in detail in the usual textbooks on general surgery. Hence there is no mention of amputations, ligations, and operations on the bones and joints of the extremities. To this extent the title of the book is misleading. What is contained in the volume is so well selected and so graphically and concisely described that we are not surprised that a new edition is called for every year. The book will form an admirable addendum and companion to any of the ordinary textbooks on surgery.

Essentials of Chemistry and Toxicology, for the Use of Students in Medicine. By R. A. Witthaus, A.M., M.D., Professor of Chemistry, Physics, and Toxicology in Cornell University. Thirteenth Edition. Revised by R. J. E. Scott, M.A., B.C.L., M.D., Author of "The State Board Examination Series." New York: William Wood & Co., 1907.

Twenty-nine years is a long life for a medical book, and when we find a book of this age constantly renewing its youth in fresh editions we are forced to believe that it possesses elements of vitality entitling it to its prolonged existence. The fact is this little book has been found by generations of students and of graduates preparing for the State examinations to be exactly what they need. It gives them such knowledge of, or rather acquaintance with, chemistry as fits them not only to pass their examinations, but, and this is the more important, to read with understanding modern medical and scientific literature. Physicians need not be chemists or physicists or pharmacologists, but they should have a knowledge of the elements of these and other sciences in order that they may pursue their own science with greater profit. In the matter of chemistry this book will give the conscientious student all that he needs to fit him for his life work. The revision for the present edition has been most satisfactorily done by one whose long experience as a teacher and mental trainer has told him what knowledge the student needs and how best to impart it to him.

Clinical Lectures on Neurasthenia. By Thomas D. Savill, M.D. Lond.; Physician to the West End Hospital for Diseases of the Nervous System, London, and to St. John's Hospital for Diseases of the Skin; formerly Medical Superintendent to the Paddington Infirmary, and Medical Officer to the Workhouse; Examiner in Medicine in the University of Glasgow; Assistant Physician and Pathologist to the West London Hospital, etc., etc. Third (Revised and Enlarged) Edition. New York: William Wood & Co., 1907.

The fact that a book on neurasthenia has reached its third edition, in seven years, with much contemporary literature on the subject, may be considered, fairly, as an indication of its popularity and merit. The present edition retains the plan of the previous one, with amplifications and elaborations, and the addition of fresh data and illustrative cases. A new chapter on Etiology and Prognosis, based upon a detailed analysis of a hundred cases, has been added. Bibliography is brought up to date. The author adheres strongly to his ideas on the autotoxic origin of many cases of neurasthenia, while acknowledging a mental element in a certain proportion of cases, in causation as well as symptoms. The chapters on Diagnosis, Pathology, and Treatment have been considerably amplified. In studying the pathology of the disease clinical methods only, of course, are available. Toxemia, malnutrition, fatigue, emotional shock, traumatism, etc., are considered interestingly and at length. The chapter on the mental symptoms of neurasthenia and their differentiation from insanity is interesting, but somewhat confusing from a Kraepelinian point of view on account of adherence to an earlier classification of the latter disease. The book is convenient in size, moderate in price, entertainingly written, and will be found useful, especially to the general practitioner.

Epilepsy, A Study of the Idiopathic Disease. By William Aldren Turner, M.D. Edin., Fellow of the Royal College of Physicians of London; Physician to Out-Patients, the National Hospital for the Paralyzed and Epileptic, Queen Square, and King's College Hospital, London; Visiting Physician, the Colony for Epileptics, Chalfont-St. Peter; and Physician to King Edward VII.'s Hospital for Officers. London: Macmillan & Co., Limited; New York: The Macmillan Company, 1907.

Portions of this work have appeared from time to time in the "Transactions of the Royal Medical and Chirurgical Society of London." The author's observations are based upon the study of a thousand cases of epilepsy seen at the Queen Square Hospital in London and in the Colony for Epileptics, Chalfont-St. Peter. Profuse references are made in the book, in footnotes, to the works of others. Discussion of the subject of the mechanism of convulsions is omitted, the physiological problems involved being considered not yet definitely established. The author is very conservative also in his figures and on all points still under investigation. The reviewer had a slight acquaintance with Dr. Turner at Queen Square and can vouch for him as a careful and conscientious observer. The book is a very clear exposition of the subject of epilepsy and will be found a convenient and promising clinical work. Many chapters have brief "conclusions," which are handy for reference, an example which might be profitably emulated by other writers. The chapter on the Pathology of Epilepsy is contributed by Dr. John Turner of the Essex County (England) Asylum, and embodies some original investigations on the subject along lines of hypotheses by the great Hughlings Jackson.

The Drink Problem in Its Medico-Sociological Aspects. By Fourteen Medical Authorities. Edited by T. N. Kelynack, M.D., M.R.C.P., Honorary Secretary of the Society for the Study of Inebriety; Editor of *The British Journal of Inebriety*. With two diagrams. New York: E. P. Dutton & Co., 1907.

The drink problem is essentially a medicosociological problem, and it is from this standpoint that the subject is viewed in this volume. It is in a great measure a pioneer work, and it may be claimed that as regards the multiplicity of its contributors as well as in several other respects it is unique. An attempt has been made to deal with the subject in a strictly scientific spirit and to present the whole question in a comprehensive series of authoritative chapters, each being written by a specially qualified medical expert. The main purpose has been to present principles and indicate laws governing the drink problem. This problem has remained unsolved, and continues to offer one of the most serious and baffling obstacles to man's up-climbing. It was for the writers to face the problem as it presents itself to-day, and to bring to bear in their task the resources of modern methods of scientific inquiry. This they have done well, but candor compels us to say that the problem still exists.

The Essentials of Histology, Descriptive and Practical. For the Use of Students. By Edward A. Schäfer, F.R.S., Professor of Physiology in University College, London. New (Seventh) Edition, Revised and Enlarged. Philadelphia and New York: Lea Brothers & Co., 1907.

For the sake of convenience, the book is divided into fifty lessons, each of which is supposed to occupy from one to three hours. A few of the preparations cannot well be made by the class, but it was thought advisable not to injure the completeness of the work by omitting mention of them. The present edition has been considerably enlarged and a new feature is the printing of many of the illustrations in color. The fact that this work has reached its seventh edition is evidence of its popularity with teachers.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Fifty-eighth Annual Session, Held at Atlantic City, June 3, 4, 5, 6, and 7, 1907.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page 162.*)

SECTION OF OBSTETRICS AND DISEASES OF WOMEN.

Ovary in the Inguinal Canal.—Dr. J. H. CARSTENS of Detroit presented the paper on this subject and reported the case of a girl, about sixteen years of age, who had had hernia since childhood, that began to enlarge with puberty. She suffered at menstruation and from the hernia. With operation she made an uneventful recovery.

Prolapse of the Ovary and Its Treatment.—Dr. GEORGE G. WARD, JR., of New York presented the technique and results of fixing the prolapsed ovary by means of a button put through the broad ligament. He said he did not claim it as his operation, but one that was done by Dr. Barrows of New York and Dr. Mauclaire of Paris, and for this reason he called it the Mauclaire-Barrows operation. This operation prevented recurrent prolapse, but did not prevent the woman from becoming pregnant. Dr. Barrows had reported two failures out of sixty cases; in one of these he found gonorrheal inflammation, and in the other he removed the ovary without giving relief.

Dr. D. TOD GILLIAM said he was much interested in the operation as described. It left the woman in good condition and able to become pregnant, and relieved a condition that often existed in the old operation—*i. e.* discomfort from the dragging of the suspended ovary.

Dr. WALTER B. DORSETT said we must remember that when the ovary was prolapsed the uterus was retroverted and must be corrected.

Dr. H. J. BOLDT said not all ovaries that were prolapsed gave symptoms, and again in some cases the simple prolapse gave rise to serious symptoms.

Gonorrhea in Women.—Dr. H. J. BOLDT in this paper said the seriousness of gonorrhea in women was noted as early as 1857, but its gravity was not recognized by the profession under Noegerath's monograph in 1892. The gonococci were extremely sensitive to dryness, but when surrounded by moisture they retained their virulence for a long time, and the smallest amount of the secretion placed upon a mucous membrane would produce a virulent form of gonorrhea. There was no immunity. Chronic gonorrhea remained infectious for years, and so long as the gonococci could be found by the most modern methods there was danger of infection. The usual site of infection in the female was the urethra, but any part might become infected. In the adult female the vaginal wall was not so frequently the site of gonorrhea. The microrganism penetrated the membrane rapidly, and there were usually signs of inflammation within twenty four hours. When there was abscess formation it was due to mixed infection, usually *Staphylococcus pyogenes aureus* with the gonococci. The supposition that the os internum offered a barrier to the gonococci had been proven erroneous, and the uterus was, next to the urethra, the most common seat of infection. In the early stages of urethral gonorrhea the patient seldom complained of anything more than burning sensation on micturition, and the duration of the disease varied from three to six weeks, or even longer. But so long as the infection remained in the urethra, and the patient kept herself clean and refrained from coitus, the majority got well without any special treatment. It was not wise, however, to rely on spontaneous cures, for many cases proved extremely obstinate.

Dr. Boldt said the gonorrhea might remain limited to the cervical canal or extend to the Fallopian tubes, and sometimes this extension was very rapid. Some of these patients make a quick recovery and subsequently became pregnant; others became chronic invalids. Pyosalpinx might be the result of the inflammation, and produced sterility as a rule. An infection before conception might give little trouble and few symptoms, but after delivery it might extend and even cause peritonitis. Infection might take place during pregnancy, and not give rise to serious symptoms more than a purulent leucorrhea. Dr. Boldt wanted to place himself on record as to the spread of gonorrhea—that it was impossible to prevent it by the method of police inspection as practised in many European cities. In this way only the acute and subacute cases were detected.

Unrecognized Gonorrhea in the Female.—Dr. SAMUEL WYLLIS BANDLER said gonorrhea was easily recognized in the male, but not so readily in the female. An acute urethritis might cause so little inconvenience in the female that the physician was not consulted, and the disease had a tendency to heal in six to eight weeks. Many women came to the physician suffering from chronic urethritis without evidence of genital lesions. The usual location of gonorrhea might prevent its recognition at that particular point. Involvement of the anus and rectum was not so rare as often thought. A frequent cause of failure to recognize the existence of gonorrhea was the mildness of the symptoms, and because the original characteristics had worn off in the course of time. The finding of purulent secretion and absence of gonococci did not exclude gonorrhea. In women it was difficult to made a diagnosis, for the physician was limited to frequent microscopic examinations and there were other bacteria that entered into the condition, and the cervical mucus often made the discovery of the gonococcus almost impossible. The use of the microscope often prevented the diagnosis rather than aided the diagnosis of chronic cases, for there was a tendency to exclude the gonococcus as an etiological factor when it was not found at once. There were certain cervical changes that were important. When erosions of the cervix existed in the nulliparæ, genorrhea must be considered. Parametritis posterior was a frequent condition, especially in multiparæ, and in many cases revealed the presence of gonococci. When it continued, there resulted a sclerosis of the uterosacral ligaments on one or both sides.

Dr. Bandler said many observers would not admit a difference in the virulence of gonococci, explaining the difference in the resisting power of the patient or in the location; but he was of the opinion, from clinical experience, that acute gonorrhea in the female was contracted from an acute gonorrhea in the male, and that the subacute form likewise came from the subacute form in the male. The subacute form had none of the symptoms of the acute, and often presented only a discharge.

Dr. REUBEN PETERSON said there were two varieties: One where there was very little pus in the tubes, but the tubes and ovaries were bound down by adhesions; a second in which there was double ovarian abscess.

Dr. TABOR JOHNSON said that 75 to 95 per cent. of those cases that required operation were due to the gonococci, and 50 per cent. of all the cases all over the world were due to this cause. A great number of women suffered from infection from their husbands, and many cases of sterility were due to gonorrheal effect upon the mucous membrane. The question of race suicide was one largely affected by this disease.

Dr. EDGAR GARCEAU said ten years ago he was in Paris, and the mode of operation then was per vaginam; but now that was out of date and not to be considered. He thought many would hesitate to make an abdominal incision where the patient was *in extremis;* but there might be drainage through the vagina and afterward, if necessary, an abdominal operation.

Dr. CHARLES S. BACON said the microscope had proved of great assistance, but in many cases there was absence of the gonococci and it became necessary to use every pos-

sible means of diagnosis. The treatment of the vaginal tract from the uterus down was very unsatisfactory.

Dr. Laura H. Branson said she had noted the statement in journals that 15 per cent. in men and in women 75 per cent. of sterility was due to gonorrhea. She would call attention to one feature that might aid in the diagnosis, and that was stricture of the female urethra. The stricture itself might be the only symptom, and in several cases she had been able to trace a history of infection from this one symptom.

Dr. Price said he appreciated the importance of the subject, and he thought the women physicians of the country should be especially interested in it. He was glad that there were now societies organized for the protection of the home and society. He did not think the curette was of much assistance in determining the condition, nor did he favor the vaginal route. He thought nature and her methods were the best. In 10 per cent. of the cases there was obstruction, adhesions, etc., that had to be relieved, and in the vaginal route this could not be done satisfactorily.

Dr. P. A. Harris said he thought the curette ought to be limited to a few cases that had been passed upon by a board of examiners. He thought no one would criticise Dr. Peterson's stand where the woman was *in extremis*, or demanded it. There were many cases of unrecognized gonorrhea in women, and that was the great factor in sterility. It was also a great factor in ectopic gestation.

Dr. Daniel H. Craig said he did not know any field in which so much was taken for granted as in gonorrhea in women, and when no other cause was found for a condition it was attributed to gonorrhea. He said he had been surprised at the number of times there had not been gonorrhea when it was expected, and he thought many cases were being classed where they did not belong at all.

Dr. T. S. Cullen said that in four cases in which there were pus tubes there might be one case of endometretis, and the fact that the endometrium was often normal spoke against the use of the curette.

Dr. W. H. Chandler said that lactic acid could be injected into the mucous membrane for the destruction of the gonococci, and if done slowly it would not produce sloughing. He though to dilate and curette was simply extending the infection.

Dr. Boldt said that Dr. Peterson's stand was correct, and many patients could be saved by drainage that could not stand an operation.

Dr. Bandler said he thought there might be a mild form due to the resistance of the individual, but oftener it was due to lack of virulence in the bacteria.

Subtotal Abdominal Hysterectomy, with Total Excision of the Gland-bearing Tissue of the Cervix and a Perfected Restoration of the Supporting Ligaments.—Dr. William F. Metcalf read this paper and gave a history of the development of abdominal hysterectomy, and described the technique of the operation. He said that after removing the entire gland-bearing tissue the ligamentary supports were restored; the peritoneal flap previously removed from the anterior surface of the uterus was thrown over the hummock, thus forming a support for the bladder. Dr. Metcalf also reported deductions from 300 cases of hysterectomies for inflammatory conditions.

Plastic Surgery of the Pelvic Structures.—Dr. Henry O. Marcy discussed the reconstruction of the pelvic peritoneum after oblation of the uterus and its appendages, in order to leave as far as possible an undamaged peritoneal covering. He advocated the free dissection of the vaginal structures when necessary for the restoration of subjacent structures, as in hernia of the bladder, vesicovaginal fistula, or cystocele. Dr. Marcy described the technique he employed in restoration of the perineum in incomplete and complete laceration, by lateral dissection to the vaginal muscle and the rejoining of the torn structures. He said the use of the buried animal suture was the important factor in the technique for the plastic restoration of this group of injuries.

Buried Sutures and Ligatures, Their Material and Proper Use.—Dr. Walter B. Chase said that objections had been made to catgut that it was impossible to render sterile; that it lacked proper tensile resistance; that it untied, and that the time it survived in the tissue was not adequate. Dr. Chase claimed by bacteriological tests that it could be rendered uniformly sterile, and that the treatment did not injure its tensile strength. The plain, chromicized catgut would secure blood-vessels and other tissues for a period sufficient for the establishment of permanent union. Furthermore, the unabsorbable material for buried sutures had no superiority over catgut, and the too tense tying of ligatures and sutures was not an imaginay evil, but a serious one.

Some Advances in Ureteral and Renal Diagnosis.—Dr. Charles Lester Leonard said the improved methods of diagnosis had resulted in a clearer differentiation between the symptoms that had been considered identical, and in a more accurate localization and knowledge of the character of the lesion. The exact localization of calculi had led to a grouping of symptoms about the most common seat of impaction, and a comparative study of those symptoms led to conclusions that were valuable in determining other bodies than calculi in the urinary tract. At present the status of diagnosis in urinary calculus was much improved owing to the further use of the Roentgen ray. Dr. Leonard said that the symptoms were not sufficient in themselves, but after obtaining all the data possible it was necessary to employ the Roentgenogram for confirmation. The Roentgen-ray was not enough in itself to make diagnosis, and must be combined with the use of the waxed catheter and the consideration of the symptoms too. The Roentgenogram must be well interpreted, and not every one could do that. It might be a beautiful picture, but deceptive. It was necessary to show the entire urinary tract. The plate should be 12x20, and the diagnosis made by the use of several pictures. In 156 cases the total errors were less than 3 per cent., and a positive diagnosis was made in 106 cases.

Surgical Treatment of Ureteral Calculus in the Female.—Dr. Edgar Garceau in this paper said the ureter in the male differed from that in the female on account of the anatomical relations. The straight ureter in the male and its position in the pelvis made it comparatively easy of access through an extraperitoneal incision. In the female the broad ligament above the most dependent portion of the ureter made it much more difficult to reach. The following routes were to be considered in the treatment of stone in the ureter: transperitoneal, transperitoneal and extraperitoneal combined, hypogastric, urethrovesical, rectal, and vaginal. He though the vaginal should be selected when possible. When the stone was impacted between the base of the broad ligament and the bladder it was accessible through the vagina in most cases; but when located between the superior strait and the base of the broad ligament it was very difficult. The vaginal operations were: Simple incision through the vaginal wall, combined extraperitoneal and vaginal incision, crushing the stone in the ureter through the vagina, Doyen's operation through the anterior cul-de-sac, and the author's operation through the anterior cul-de-sac and vagina. The question as to when to operate was a difficult one to decide, for a stone might remain impacted quite a while and then pass to the bladder without change in the kidney. While all stones did not block the urine entirely, an expectant treatment was dangerous. Dr. Garceau discussed the various operations, and said that he wished to describe one that he had devised in an urgent case. The patient had suffered agony for a week trying to pass a stone impacted in the left ureter. She had just been delivered of a child with an operation that involved a great loss of blood, and while the vaginal route seemed impractical, he decided that

it was impossible to go through the abdominal wall. He decided to try pushing the stone toward the vagina and thus let it act as a guide for his incision. He incised the anterior cul-de-sac, pushed the peritoneum between the bladder and uterus; everted the broad ligament backward with the tip of his finger; caught the stone with the end of his finger, forced it down toward the vaginal outlet, cut upon it with a small incision, and squeezed it out like a stone from a ripe cherry. The operation took only ten minutes.

Dr. HUNTER of Washington said it was significant of advancement that we had so many aids in the diagnosis of stone. Dr. Leonard had probably set forth all the methods of importance, and he was pleased that he advised the use of all of them. In his own work he was never satisfied with the *x*-ray picture alone, or the waxed catheter alone. Sometimes the *x*-ray missed a large stone when imbedded in fibrous tissue, and at times it might find a stone that did not exist.

Dr. PERCY BROWN said that he would like to emphasize the importance of preparing the patient before taking a Roentgenogram. This preparation should begin twenty-four hours before by giving a cathartic and cleaning out the lower bowel. The patient should take food sparingly at the previous meal. Phleboliths should be considered seriously. He had been surprised to see how small a phlebolith would produce a shadow.

Dr. BRANSFORD LEWIS said he was glad to see that Dr. Leonard left room for doubt as to diagnosis, and at the same time suggested care in the conclusions derived from the *x*-ray, for a mistake would arise even with the best. He remembered a case where a Roentgenogram demonstrated an object in the right ureter, and a diagnosis of a stone was made; but on incision no stone was found. He cited another case, in which Dr. Seely detected a little object that proved to be an accretion in the end of the appendix, and removed it. He never subscribed to the infallability of the *x*-ray or the waxed catheter. As to treatment, he would like to ask what was the use of making an incision if the calculus could be gotten out without an operation, and many could be removed by working through the cystoscope.

Dr. CHARLES P. NOBLE said we ought to locate the stone with the *x*-ray and the catheter without going back to the dark ages, and make two incisions instead of one incision, or cut through the rectus muscle and get all the room needed.

Cystocele.—Dr. CHARLES P. NOBLE presented a paper upon this subject. Cystocele was a hernia of the bladder into or through the vaginal opening, usually described as prolapse of the anterior vaginal and bladder walls. It was his opinion that the tonic condition of the abdominal muscle, the intraabdominal pressure, and the lack of proper anatomical supporting ligaments of the uterus and the bladder, which played their rôle in the maintenance of position of the pelvic organs, were important factors; but the greatest factor was the want of integrity in the sacral segment of the pelvic floor. This was why cystocele occurred secondary to impairment of the pelvic floor. The exception was in cases of marked muscular relaxation of the pelvic tissue, or absorption of the perivaginal fat. Causative injuries of the pelvic floor involved laceration of the pelvic muscles and fascia. As a result, a pouch of the bladder, greater or less in size, was pushed down, together with the anterior vaginal walls, into the vaginal outlet, or entirely outside of the vaginal canal. Cystocele was complicated in many cases, and often involved restoring the entire vaginal walls with as much detachment of the bladder as might permit it to rise to its normal condition in the pelvis. The ligaments of the bladder were of service in supporting it in position, but in these cases the bladder itself fell with the uterus, and the pelvic contents were supported by the sacral segment of the pelvic floor. The position of the uterus was of prime importance. If it were retroverted, intraabdominal pressure tended to force the uterus down and out of the vaginal canal, and the entire vaginal walls were thus forced down.

Dr. Noble said that the chief credit for placing this operation upon a sound basis was due to Dr. Hadra of Texas, who was the first to recognize that the way to cure cystocele was to incise the anterior vaginal wall, detach the bladder from the entire face of the uterus, and laterally from the vagina, sufficiently to permit it to rise in the pelvis; then resect the anterior vaginal wall to get rid of the excess of tissue, and to fill this by suturing the anterior vaginal wall up to the anterior face of the cervix, so that it might become attached and thus prevent the descent of the bladder. The many operations since introduced were based upon the principle set forth by Hadra.

Simplified Method of Operating for Cystocele.—Dr. D. TODD GILLIAM, discussing this operation, said it consisted of: (1) A denudation of the most prominent part of the cystocele; (2) dissecting flaps from the vaginal wall on either side of the denuded area with which to cover it; (3) bringing the flaps together over the denuded area and suturing them to it and to each other. The technique was: (1) Lift up the redundant tissues and, by means of tenacula or tissue forceps, gather them into a longitudinal fold along the median line of the anterior vaginal wall; (2) make an incision on one side of and at the base of the fold at or near the median line; this incision should extend from within a like distance of the other end; (3) carry the incision down through the fascia to the muscularis of the bladder; (4) make a similar incision on the other side of the fold; (5) by blunt dissection separate the bladder from the vaginal wall from the incision outward to the sulci; (6) convert the two separate layers of the vaginal wall into flaps by cutting outward from the upper and lower extremities of the incisions toward the sulci; (7) denude the area between the incisions; (8) draw the flaps over the denuded area and suture them to it and to each other from below upward.

Dr. J. RIDDLE GOFFE said that there was little new in the operation as presented. His position had been that it was wrong, and he thought that nature's plan of suspension was the best. We accepted nature's method of suspension of all the organs until we got to the pelvis, and then seemed to forget it. The perineum was not intended as a support of the organs, and only when it was torn did it have any influence, and then it acted against nature. Cystocele might occur in virgins. The bladder was held in place by ligaments, and not by props as claimed. Even in complete laceration of the perineum the organs stayed in place, and building up the floor of the pelvis was futile in holding the bladder and uterus in position. The bladder was supported by and hung from the uterus, and the logical operation would be to put the uterus in position, dissect the bladder, and stitch it higher up to the uterus. Thus it became suspended as nature intended.

Dr. EDWARD REYNOLDS said all believed in the suspension of the organs of the pelvis; but he thought that the perineum also acted as a support.

Dr. I. S. STONE said that he believed in many things with Dr. Goffe, but it seemed that he was a little radical. The speaker had seen cases where the perineum had been entirely torn, yet the uterus and tissues were uninjured. He had been satisfied with the operation for the supporting of the uterus.

Dr. NOBLE said that he had not seen more than half a dozen cystoceles in virgins in twenty years, and nearly all of the cases were found in multiparæ. It should be remembered that complete laceration did not injure the levator muscles. In the operation he described the bladder rose in the pelvis and there were no puckers; but Dr. Goffe put in sutures and *made* puckers.

Dr. GILLIAM said that he was surprised that a man of

such great learning along other lines as Dr. Goffe could see nothing but suspension. Remove the abdominal walls and the viscera would not remain.

Salpingitis Caused by Appendicitis.—Dr. I. S. Stone presented this paper. He said that there were two methods of transmission of the infection: (1) By the lymph channels, or the blood-vessels; (2) by direct contact, as when the pus from a perforated appendix was applied to the fimbriated extremity or directly discharged into the tube. The following case was illustrative of the subject: Patient's age, 35; white; two children; previous health good, and seen with the family physician three days after the beginning of appendicitis. It was six miles to a hospital, but they decided to operate if patient could be got there. Pulse, 135; temperature, 102.5°; no distention; the bowels well cared for by enema; in six days the temperature was normal. He then operated and found necrosis of the appendix and a portion of the cecum, which appeared the size of a silver dollar. The pelvis was infected. He decided to delay operation, replaced the tube, and closed the abdomen. The patient improved, until the temperature rose and showed the right side distended with pus. He opened per vaginam and found pus with the odor of that in the pelvis at the first operation. The tube on the left side behaved the same way and was opened. The patient recovered. Dr. Stone said it might be considered impossible for salpingitis to cause appendicitis, but in the case cited he had found large pus tubes, perforated and gangrenous appendix, and in all the colon bacillus which indicated an intestinal origin. He thought it was the rule for the Fallopian tube to become infected secondarily.

The Early Diagnosis of Tubal Pregnancy.—Dr. Philander A. Harris read this paper. He said that it was formerly supposed that the first symptoms of ectopic gestation were pallor, a weak and rapid pulse, subnormal temperature, and often syncope. However, it was only in the exceptional cases that these were the first untoward symptoms, and in most cases the patients had other symptoms that caused them sufficient discomfort to send for the physician days or even weeks before the serious symptoms mentioned appeared. Colicky pains, atypical menstruation, metrorrhagia were special symptoms. For diagnosis it was very necessary to get a correct history of the patients' past and present menstrual habits, for the symptoms connected with this condition were of vital importance. In nearly all cases the family physician was the first to be consulted, and it was of greatest importance that he familiarize himself with all the facts that would lead to a correct diagnosis. Twenty-nine out of thirty cases presented symptoms from which a diagnosis could be made previous to what he called the tragic stage. In 130 cases, 90 per cent. consulted physicians before the tragic stage for symptoms referring to pelvic trouble. Many received medical attention for a term of several weeks before the tragic stage. Many were wrongly assured and relied for days or weeks on false hopes. Some were treated for abortion, and about 20 per cent were subjected to curettage for cure of metrorrhagia. Dr. Harris said that 99 per cent. of the cases treated in the nontragic stage recovered, but very few treated in the tragic stage lived. It was, therefore, of vital importance that the early diagnosis be made, and this responsibility rested largely on the family physician. He wanted to emphasize especially two symptoms—pain and atypical menstruation.

Dr. C. Jeff Miller wished to ask whether Dr. Harris found tenderness on palpation, and if he advocated palpation.

Dr. Florus Lawrence said the paper as well as the subject was one of great importance, and he agreed with Dr. Harris that the time for diagnosis was before rupture took place. Three cases had come under his care in a short time, and in every one there was a history of previous tubal disease. It was a question whether the operator should leave the other tube. In one case in which the tube was left it had to be operated on within fourteen months for the same trouble. In two other cases the patients died on second extrauterine pregnancy. He thought that pain, intermittent in character; uneasiness, breast changes more marked than in normal pregnancies, and irregular flowing were symptoms of importance.

Dr. Carson said it seemed to him that the diagnosis was not easy. In many cases the woman did not know there was anything the matter, and probably gave a history of having had "attacks" before.

Dr. Harris said in conclusion that if there were nine correct diagnoses out of ten it was good enough. He was accustomed to say that he was sometimes wrong. As to tenderness previous to rupture, he thought tenderness would be found in nearly every case; but the examiner should exercise great care or he would produce a hemorrhage.

Constitutional Ill-Equipment of the Patient as a Factor in Determining the Performance of the Primary Cesarean Section.—Dr. Edward Reynolds said that in 289 cases, under different operators, and with different methods, in various parts of the world, 49 belonged to the first class, *i. e.* after expulsive efforts had failed to drive the head through the pelvic brim; 158 belonged to the second class, *i. e.* after a moderately full test in labor, but before exhaustion; 82 in the third class, *i. e.* before labor. Including one patient in the third class who died as a result of rupture of sutures, the fault of the attendant, the mortality was 12 per cent. in the first class, 8 per cent. in the second, and 1.2 per cent. in the third class. Mortality then might be estimated by the amount of labor endured before the operation. Late operations had become discredited, and never were performed by men of experience who had the care of the patient from the start; but the secondary operation was still too highly in favor. The performance of the primary operation had become the custom all over the world. He said that Dr. Edgar stated that the mortality of cesarean section must be admitted to be proportionate to the length of labor endured before its employment, but as the mortality rose very little during the first few hours of labor, a slight test in labor might be considered justifiable. Dr. Reynolds said that there was no doubt of the truth of the statement, but at the same time the slight test of labor would prove very little concerning the ability of the patient to perform the act. He considered that it was of importance to decide for or against cesarean operation before the time for labor. This might be determined by conditions of the pelvic outlet, especially the pelvic bones, and by the previous history, as when multiparæ had had difficult labors before, with death of the child, etc. Then, too, there was a difference in the ability of women to endure pain, and this would influence the decision as to what to do. He would give it as a surgical axiom that it was always wise to recommend a relatively safe operation rather than to subject the patient to the chances of a late operation for a doubtful and uncertain condition.

The Delivery of Debilitated Women; with Especial Reference to the Interest of the Child.—Dr. Edward P. Davis presented a paper on this subject. He said that labor was a spontaneous and successful process which prohibited interference, but its indiscriminate application to obstetrics had cost many lives. Many women were not able to give birth to children unless special consideration was given to each case. For instance, when a frail woman had a large husband the physician might attempt to modify the size of the child by means of diet, encourage premature spontaneous labor by free exercise, interrupt pregnancy at a time selected by himself, or allow the woman to go to term and be prepared for whatever condition might arise. He thought that dieting the patient was of doubtful benefit. Many cases gave good results where labor was induced at a time set by the physician. Pubiotomy had attracted attention as a substitute for abdominal operation, and in eight cases he

had had fairly good results, but not so good as in abdominal operations. He thought that delivery by abdominal section, especially in selected cases, compared well with other methods for both mother and child.

A Bimanual Method of Rotation in Occipitoposterior Vertex.—Dr. William D. Porter explained the technique of using the hands instead of the forceps in rotating the head. He said that, for instance, when the occiput was in the right posterior position, by inserting the left hand and making pressure from above with the right hand, and then untwisting the left arm, the head could be swept around to the position desired. This method of inserting the hand was important, as having the arm turned so that it gave greater strength was one of the important factors of a successful interference. He had found the method very successful, without injury to mother or child, and one that avoided all possibility of injury to either.

Syncytium.—Dr. Laura H. Branson read a paper on this subject. She said the syncytial tissue was of fetal origin and had the power of proliferation. The chorionic villi, or parts of them, together with their epithelial covering, might normally circulate in the vascular and lymphatic circulation of their host. It was possible for this circulation to take place during the period of pregnancy, from the formation of the chorionic villi to the termination of labor. This epithelial covering of the chorionic villi had the power to proliferate, and this proliferation might take place during the entire life cycle of the syncytium and Langhans cells. The syncytium had a physiological function, and if foiled in this its pathology might prove detrimental to both fetus and host. It was the prime factor in the production of a peculiar neoplasm, whose history placed it in a class by itself—syncytiosum malignum. The theory of the syncytium being a prime factor in the production of eclampsia was one that was upheld by recent investigations. Hepatic changes were the rule and not the exception in eclampsia. Dr. Branson said further that malignant neoplasms of pregnancy had an eroding action upon the structures of the uterus, and this was the nature of the chorionic epithelium covering the villi. Normally, chorionic epithelium was also one of the constituents of these neoplasms. It was reasonable, therefore, to conclude that their origin was the same, and that this activity remained in force in the neoplasm. She thought that chemistry would aid in determining the products of different cell processes, and the future was full of interesting subjects of research along the lines suggested.

Dr. I. S. Stone said it was the first time he was ever present when a paper was presented upon the subject under consideration. One practical point was that it showed the necessity of knowing all about anatomy and the minute physiology of the body. The works of Veit upon this subject gave about all there was upon this subject up to the present time, but Dr. Branson's paper showed extensive personal research and study. It was wonderful how these cells attacked the vessels at the proper time; but they did not stop at the proper time—the process went on to a malignancy of the most fatal kind.

Sarcoma of the Uterus, with Report of Nine Cases.—Dr. Ellice McDonald said that discussion of this subject was rare up to the last nine years. In 2,200 cases reported by Dr. Noble there were about 2 per cent. of the fibroid tumors that were fibromyoma. Sarcoma of the cervix was very rare. Sarcoma of the fundus were divided into the diffused and circumscribed, and the diffused type was the most malignant and caused much hypertrophy. The usual result was hemorrhage, metastasis, and changes in the surrounding tissues. In 168 cases 45 were subperitoneal and 63 were submucous. The submucous tumor was usually a fleshy mass. By straining it had been shown that the muscle fiber went through a transitional stage. Dr. McDonald showed specimens in which the change had taken place—four cases in which the fibrous tumor had changed to sarcoma. It could not be said that sarcoma was always from a fibroma when together, but it was probably true. In examining specimens, it was important to cut them in a way to see the different parts of the tumor and submit them to a microscopical examination. It would be readily seen that, as the fibroma often changed into sarcoma, it was the better judgment to remove the fibroma.

Dr. Noble said we had learned that sarcoma was more common than usually believed. He had had four cases, and only during the last seven years had he made it a rule to have all specimens examined; previous to that he had only the suspicious looking ones examined. He thought there was no doubt that if the fibroid tumors were systematically examined more sarcomas would be found.

Dr. Craig said he had had three cases of sarcoma of the uterus; one was early, and the second further advanced. One woman died of metastasis and recurrence, the other recovered.

Dr. Carsons said he had seen a number of cases of fibroid tumors that were later malignant and fatal. He thought these tumors should be removed, for he held that the woman with a fibroid tumor was in danger.

Dr. Walter B. Dorsett said that in years past he had postponed operation, and pleaded guilty to having had considerable faith in electricity at one time, but now he thought there should be an operation. He had a case of a woman with a small pedunculated tumor on the fundus of the uterus. It weighed eight pounds. She developed fever and was treated for malaria. She consented to an operation after the malaria subsided; but it did not subside. She was put on the table with a pulse of 120, operated on, and a large tumor, fed by blood supply from the omentum, was found. The speaker removed it and found pus inside. The temperature then subsided and the patient recovered. He thought there was no doubt but fibroid tumors changed to sarcoma and carcinoma and the only cases where an operation should not be performed were in cases of small tumors where there was pregnancy.

Dr. Gilliam said he had always been conservative in these cases. While some might remove fibroids with a mortality of one or two per cent. he thought it averaged nearer ten per cent. When there was no trouble resulting from the tumor he left it alone.

Dr. McDonald said he had found one fibroid tumor in every seven cases examined, and if we operated on every fifth woman we would do a foolish thing. His report was based on fatal cases, and it was necessary to draw a line somewhere, though this was difficult. He thought the indications for operation should be more or less lasting, and it was his rule to operate where the tumor produced symptoms.

Officers.—The following officers were elected for the ensuing year: *Chairman*, Walter B. Dorsett, St. Louis, Mo.; *Vice-Chairman*, Charles P. Noble, Philadelphia, Pa.; *Secretary*, Walter P. Manton, Detroit, Mich.; *Delegate*, F. F. Simpson, Pittsburg, Pa.; *Alternate*, Thomas J. Watkins, Chicago, Ill.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, May 20, 1907.

The President, Dr. Thomas E. Satterthwaite, in the Chair.

Some Plain Facts About Syphilis.—Dr. L. Duncan Bulkley read this paper. (See page 213.)

Dr. Boleslaw Lapowski emphasized the great importance of diagnosis in syphilis. A correct and timely diagnosis might conserve the integrity of vital organs, such as the heart and brain, the beneficial action of specific treat-

ment preventing the development of irreparable changes. It was well to be familiar with all methods of introducing mercury into the system. Each method had its special indications, and as the main aim of treatment was the prevention of destructive tertiary manifestations, the best method was the one by which we could introduce mercury in the safest way for the patient, the physician always remaining the master of the situation, *i.e.* being able to interfere successfully in cases where the undesirable effects of mercury manifested themselves. In that respect, the inunction method answered best. Dr. Lapowski said that during the last few years our conception of some fundamental points in syphilis, such as reinfection, immunity, and the contagiousness of various syphilitic manifestations had changed.

Dr. Leonard Weber said that in 1883, in a communication read before the New York Academy of Medicine, he reported 125 cases of syphilis which had been under his care during the preceding twenty years. The treatment which he had invariably followed in those cases, and which he had found very satisfactory, was by mercurial inunctions, much more so than by the use of mercury by the mouth. In a second series of about seventy-five cases treated since that time, of which he had more or less accurate records, he had depended exclusively upon deep injections of a 10 per cent. mixture of the salicylate of mercury in albolene. The average dose of this mixture was about ten minims. He had seen no ill effects follow these deep injections, such as had been reported by some observers, and his results were even better than those obtained by the use of mercurial inunctions. Dr. Weber said he agreed entirely with Dr. Bulkley that in the treatment of syphilis we should keep in mind not alone the disease, but also the patient. The treatment had to be adapted to each case. A syphilitic who used alcohol to any great extent, or who acquired the disease late in life, was much more difficult to treat and was in greater danger than an individual who was infected early in life and who was a man of steady habits. While he did not know of any reliable statistics bearing upon the longevity of syphilitics, he had in mind some figures which were compiled by a large life insurance company in Scandinavia, which showed, among a large number of the assured, that the life expectancy of those who gave a history of syphilis was from six to ten years less than the average. While these figures might not be applicable in this country, still we all recognized the fact that many deaths were indirectly due to syphilis, and we were too apt, perhaps, to ignore certain post- or parasyphilitic lesions, especially those of the heart, which we now knew better than formerly were amenable to antisyphilitic treatment, particularly to the so-called mixed treatment.

Dr. Charles A. Kinch said there was a certain vagueness of thought among the laity, which extended somewhat even to the medical profession, regarding the identity of syphilis, and when they came in contact with a disease or manifestation which was out of the ordinary they were very apt to term it "something syphilitic." The speaker referred to a number of cases coming under his observation where syphilis had been innocently acquired, and he emphasized the fact that syphilis, even less than gonorrhea, was no longer to be looked upon as a shameful disease.

On the Transmission and Cure of Cancer.—Dr. William Seaman Bainbridge presented a paper on this subject, in which he concluded that: 1. The hereditary and congenital acquirement of cancer were subjects which required much more study before any definite conclusions could be formulated concerning them. 2. In the light of our present knowledge, they held no special element of alarm. 3. The contagiousness or infectiousness of cancer was far from proved. Evidence to support the theory of contagion or infection was so incomplete and inconclusive that the public had no reason to concern itself with it. 5. The public needed merely to be instructed to apply the same precautionary measures as should be brought to bear in the care of any ulcer or open wound. 6. The danger of the accidental acquirement of cancer was far less than that of typhoid fever, syphilis, or tuberculosis. 7. In the care of cancer cases the attendant was in much more danger of septic infection or of blood poisoning from pus organisms than of any possible acquirement of cancer. 8. The communication of cancer from man to man was so rare, if it really occurred at all, that it could practically be disregarded. 9. In cancer, as in all other diseases, attention to diet, exercise, and proper hygienic surroundings was of the utmost importance. 10. Cancer was local in its beginning. 11. When accessible, it might, in its incipiency, be removed by radical operation so perfectly that the chances were overwhelmingly in favor of its nonrecurrence. 12. Once it had advanced beyond the stage of cure, in many cases suffering might be palliated and life prolonged by surgical means. 13. While other methods of treatment might, in some cases, offer hope for the cancer victim, the evidence was conclusive that surgery, for operable cases, offered the surest means of cure.

Dr. James Ewing said he was quite in accord with all Dr. Bainbridge had said in regard to the nontransmissibility of cancer. In fact, he had not previously been aware that any one seriously believed that the disease was contagious. Certainly there were no grounds for such a belief at the present day. The so-called epidemics of cancer in human subjects had, to-day, only an historical interest. One of the most famous of these "epidemics" in literature was that described by Behla in Luckau, but it was subsequently proven that cancer was no more frequent in this than in other German towns. The increase in the deaths from cancer during recent years was largely due to improved diagnosis, and a further increase of at least 20 per cent. might still arise from this cause. If cancer was contagious, then, it was probably a parasitic disease. As a matter of fact, history showed that every type of microorganism known to medical science had at one time or another been found in cancer. The last of these were the spirochetes which had been found some time ago by Borrel in mouse tumors, and lately by Gaylord. Tyzzer, however, had shown that many mouse tumors were free from spirochetes, and that such organisms occurred in the bodies of mice free from cancer. He had himself studied many human tumors by the silver method, and had failed to find spiral organisms in any excepting ulcerated tumors, and only rarely in these. The speaker expressed the opinion that no parasite could ever be accepted as the cause of cancer until the collateral evidence of the disease favored the parasitic theory. At present not a single fact had been adduced strongly favoring the parasitic theory of cancer, and there was no analogy to support such a theory anywhere in the vegetable or animal kingdoms. Gaylord had urged the importance of certain cage "infections" among tumor mice. These must be referred to two factors, namely, the increased incidence of tumors in aged animals, and the influence of inbreeding. M. Plehn, in Munich, had recently shown that the epidemics of thyroid cancer which decimated some carp ponds in Germany were referable to the peculiar methods of inbreeding of these fish. In man neither age nor inbreeding could influence the occurrence of cancer as it did in the lower animals in captivity; hence there were no cancer epidemics in human subjects. The apparent existence of a blood immunity in mice recovering from cancer, as first shown by Gaylord and Clowes, was one of the interesting new facts bearing upon the incidence and transmissibility of the disease. The study of the condition of the successful transmission of cancer from one lower animal to another had shown that the factors determining such transmission were extremely delicate. Only two or three tumors among hundreds studied had proved transplantable even under the most favorable experimental

conditions. This result indicated that very few, if any, human tumors could be successfully transplanted to healthy human beings, even if the attempt were made with the greatest persistence and under the most favorable experimental conditions. If there were any contagious human carriers, clinical experience would long ago have proven it, as in the case of the infectious lymphosarcoma of dogs, which was quite unparalleled by any human tumor. Clinical experience was decidedly against the transmissibility of human cancer, and the idea of isolating cancer cases was not in accord with the known facts of the disease. Experimental evidence, also, had shown that it was impossible to obtain the biological conditions necessary for the successful transfer of the vast majority of malignant tumors, even among lower animals.

Dr. Ransford E. Van Gieson of Brooklyn referred to traumatism as an etiological factor in cancer.

Dr. S. P. Beebe referred to the artificial transplantation of lymphosarcoma in dogs. This type of tumor, which had been studied for a number of years in Germany and in the Loomis Laboratory, had always passed under the name of infectious lymphosarcoma in dogs, largely because it was found as a primary growth affecting the genital organs of those animals. After extended experimentation with these growths, Dr. Beebe said, they had failed to find any evidences of infection. Furthermore, they had become convinced that it was a true tumor, and not an infectious one. It invariably started from the implanted cells. It was possible to transmit this tumor by rubbing a fresh specimen upon a granulating surface, although it was less apt to grow in that way than by transplantation. If any conclusion applicable to human beings could be drawn from these experiments, it would be that only very rarely could malignant tumors be transferred from one individual to another.

The Role of the Gonococcus in Disease; the Present Status of Its Knowledge.—Dr. Robert W. Taylor presented this paper, in which he confined himself largely to the cytology of the subject. After reviewing at length the work done in connection with the gonococcus since its discovery by Neisser in 1879, Dr. Taylor said that at the present state of our knowledge the objections which were originally raised against the etiological significance of the gonococcus had been definitely overcome. Practically all the complications of gonorrhea had been demonstrated as due to the gonococcus; and certain remote effects were now brought into an obscure connection with the poisons (toxins) produced by this germ. This strictly limited etiological and clinical field was gradually becoming surrounded by highly important neighbors. The more deeply we penetrated into the knowledge of the diseases of the urethral, vaginal, and uterine mucosa, the more we were forced to realize that in addition to the most common cause of these affections, namely, the gonococcus, other bacteria must likewise be capable of producing and maintaining inflammatory processes in these regions. Within the past few years considerable attention had been directed to the cytology—the study of the finer structural detail of the cells in urethritis. In this work the methods and line of study were practically an application of the recent advances in the study of the morphology of the blood. Many facts as to the structure and development of the gonococcus had been ascertained, but there had been little decided progress made. Some observers claimed that there were many aberrant types of this microbe which differed in tinctorial and pathogenic effects from those looked upon as typical. There could be no doubt that the toxins of gonococci played a very considerable part in many diseased conditions.

Dr. Herman J. Boldt said that gonorrhea was a more serious menace to the human race than was syphilis. According to his observation, in more than 66 per cent. of women who were suffering from sterility the condition was the result of gonorrhea in the husband.

New Instruments.

A LEVER FOR THE CORRECTION OF DEFORMED FEET.*

By JOHN C. SCHAPPS, M.D.,

BUTTE, MONTANA.

LATE ORTHOPEDIC SURGEON TO THE ST. MARY'S GENERAL HOSPITAL AND THE KING'S COUNTY HOSPITAL, NEW YORK; MEMBER OF THE AMERICAN ORTHOPEDIC ASSOCIATION: ORTHOPEDIC SURGEON TO THE MURRAY HOSPITAL, ORTHOPEDIC SURGEON TO THE PAUL CLARK HOME, BUTTE, MONTANA.

Manual correction of deformed feet is frequently impossible because the part of the foot in front of the mediotarsal joint is so small that it can be grasped only by a small portion of the operator's hand, and the resistance is so great that this grasp is inadequate to overcome it. Feet large enough to be firmly grasped offer proportionately greater resistance. Some mechanical aid or a cutting operation is then necessary.

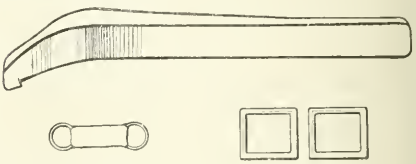

Fig. 1.—Lever, ringed webbing, and halter squares.

A congenital club foot—and this is the sort with which we have usually to deal—thoroughly corrected by stretching only, is more flexible and less liable to relapse than if the rectification had been obtained by cutting, for the essential condition is one not of passive deformity, but of active, distorting, hardening contraction. It affects a number of structures and extends through a large mass. The treatment should be directed against it and not against the shape merely. Stretching directly opposes the fundamental condition. It attacks every part of every contracted tissue. It induces the state of diffuse flexibility often the result of an accidental

sprain. It leaves the long tendons intact and free, and their muscles are capable of development.

But when the shape of the foot is rectified by cutting, much of the contracted and contracting tissue remains untouched. An open incision introduces a scar which is ultimately an additional element of

ends of the long tendons are prevented from reunion by the intervention of the scar. Their muscles in the leg cease to act upon the joints of the foot, and, having no physiological use, become

Fig. 4.—The straight end of the lever applied transversely to the forefoot for twisting either inward or outward. Two straps of three-quarter webbing pass over the foot, through the squares and buckle back on themselves. The buckles are placed at the side, the under webbing protecting the skin. The foot is well flattened down upon the lever before force is exerted. This torsion is most efficient when the foot has been brought to a right angle with the leg

incapable of development. This is more than a cosmetic defect. In the use of the lower limbs as organs of locomotion, the front part of the foot is the fixed point upon which the body is raised and

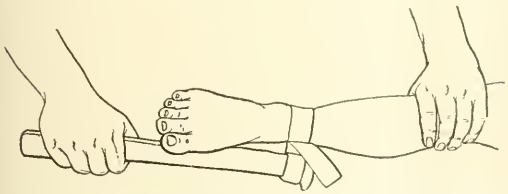

Fig. 5.—The lever applied to pry the foot laterally at the ankle. A fracture of the fibula might be easily produced, and the instrument might serve as an osteoclast, to correct the deformity which occasionally follows fracture of that bone, or in other situations.

moved forward—largely by these muscles. The imperfect gait and disability following an open operation, when the bones of the foot are in excellent relation, are produced by both muscular insufficiency and ankylosis. In operating, therefore, upon a club foot only those structures which resist an ample overcorrection and do not yield to stretching should be divided. And, whatever the method, rectification is but the beginning of treatment.

For the correction of resistant deformed feet—flat feet or club feet—I have found the simple contrivance here shown safe and serviceable. It consists of a stick of maple or other hard wood, two square iron harness rings known as halter squares, round iron rings, webbing, and strong buckles (Fig. 1). The lever is smooth, well filled and shellacked. It may be sterilized by immersion in formaldehyde or other aqueous disinfectant, and the smaller parts by steam, so that the instrument is available where a cutting operation is necessary. For use on children's feet, the dimensions are as follows: The inside width of the halter squares is 1½ inches, their inside height 1¼ inches. The lever is about 14 inches long. One end is straight and fits into the halter squares, space being left on top of the lever for webbing passing through the squares. The other end is 1¼ inches wide and notched on the under side to hold a strap. Two or 2½ inches from this end the lever is bent, and the width here is increased to 3 inches.

The lever has several applications, as shown in the accompanying illustrations. In its principal use it is strapped either anteroposteriorly or transversely to the sole in front of the mediotarsal joint. The dorsum has to bear only strap pressure. The sole, though it may never have experienced pressure, is anatomically prepared for a broad, flat contact such as this. When much force is necessary, a pad should be interposed between the skin and the wood. The straps are kept well up on the foot so that the tarsometatarsal joints are not strained. Grasping the lever, the surgeon feels that he has a firm hold upon the forefoot, and that the tarsus is engaged between two levers—the instrument and the leg. The action should be rapid with increasing force, the circulation being quickly released. Several applications are made if necessary until the resistance is thoroughly overcome.

Radiotherapeutics in Syringomyelia.—A. G. Gramegna has treated two cases of syringomyelia with applications of the *x*-rays with very encouraging results, the motor power of the patients being considerably increased after the treatment. The author states that the treatment should be begun in the early stages of the disease before there has been irreparable destruction of the nerve tissues. The essential lesion of syringomyelia is believed to be a gliomatous formation in the spinal cord, and when this has occurred the *x*-ray treatment will be of value. The effect of the rays is to destroy young cells, especially when they arise from connective tissue. Therefore, the effect on the new gliomatous tissue will be that of destruction, the pressure on the nerve fibers being relieved, and the cord returning to a normal condition. There may be a fresh formation of gliomatous tissue, and hence a recurrence of the disease demanding renewed applications of the rays. As to technique, use No. 7 Benoist rays, anticathode at thirty to thirty-five centimeters from the skin, with lateral irradiation through the lamina of the vertebræ, alternating the two sides, and covering the opposite of the body with lead shields. Sittings should be on alternate days. Two or three series of eight to ten sittings at the most, with intervals of several days between the sittings. When improvement is obtained treatment should be repeated after some time.—*Rivista Critica di Clinica Medica.*

THE TREATMENT OF SURGICAL TUBERCULOSIS BY HYPEREMIA (BIER).*

By V. SCHMIEDEN, M.D.,

BONN, GERMANY.

PRIVATDOCENT FUER CHIRURGIE, OBERARZT AT THE SURGICAL CLINIC OF THE UNIVERSITY OF BONN.

I APPEAR before you in place of my chief, Professor Bier, in order to speak to you about the treatment of surgical tuberculosis by means of hyperemia and to demonstrate to you the technique. This I am glad to do, and I hope my words will help to further the new teachings of which Professor Bier is the author.

Professor Bier's treatment of inflammatory processes is in marked contrast to that of previous teaching in that this treatment does not combat the infection, but rather increases the normal reaction of the part. Bier increases, artificially, redness, swelling, and heat, three of the cardinal symptoms of inflammation. These are, according to his teaching, none other than the natural weapons of the organism. He who applies the ice bag to a phlegmon, or he who by elevation of the part removes the swelling, only hinders the organism in its own efforts at healing and assists the bacteria in their work of destruction.

If Bier's teaching is founded upon facts—and it is founded upon facts—then must its practical application be carried into surgical therapeutics. No one at present gives drugs, to reduce the fever, for the reason that the increased temperature is part of the healing process. Since Bier's investigations we no longer suppress the inflammation, we rather increase it.

At first Bier found real difficulties only in the technique. He discovered that we must use *the blood* for increasing the inflammation. Therefore he increased the hyperemia and at the same time decreased the flow of blood, which is already decreased in every inflammatory process. This is the clear train of thought, which gave rise to this treatment by hyperemia.

Tuberculosis, especially tuberculosis of joints, was the first disease which Bier treated with his hyperemia band (Stauungsbinde). To-day this band is used in many other diseases, in some of which better results are obtained than in tuberculosis, although the results secured in tuberculosis are very good indeed.

The technique at first was varied, as it was difficult to arrive at the proper degree of hyperemia and to determine how long it should in each case be applied. It is absolutely wrong to think that if a little is good more is better. It is to be regretted that beginners, who have not thoroughly mastered the technique, make this mistake; and to this fact are due the poor results of which we hear.

In order that there may be no misundertanding, I will begin with a description of the technique, which is of greatest importance.

One takes a broad (6 cm.) soft rubber bandage, applying it slowly and evenly around the extremity, proximally to, but not too close to the tuberculous joint. (Tuberculosis of the wrist joint, for instance, is treated regularly with the bandage above the elbow.) In winding the bandage, each turn overlaps the preceding one, in order that the pressure may be evenly divided and over a sufficient area. *These bandages must not cause pain either at the place of application or in the diseased joint.*

The extremity below the bandage soon begins to swell in a moderate degree and assumes a bluish-red color; *it remains warm, at least as warm as the other limb, and the pulse remains entirely unchanged.* Thus we do not produce a stoppage of the blood current, but rather increase its volume, this being due to our interfering with the normal return of the blood on its way to the heart.

This so simple technique is many times poorly practised. Patients who have been subjected to treatment by hyperemia at the hands of others have often told us that the pain produced by such treatment was so severe that it was impossible for them to continue it. It is evident that such treatment is not in accordance with Bier's teaching and naturally can have no good effect.

The hyperemia bandage in tuberculosis is applied only for a few hours per day. We apply it from one to four hours in the following manner: Once for an hour or once for two hours; or twice for an hour or twice for two hours. If the patient has a tender skin we change the location of the bandage. During the hyperemic treatment we remove all other bandages and place a piece of sterile gauze or a towel over discharging fistulæ. A pressing bandage of any sort would render the hyperemia treatment impossible.

Further, one must not keep the joint in fixation. In tuberculosis of the articulations of the upper extremity we let the patients use at most only a sling for support, and soon allow them to make slight exercises with the arm, as, for instance, in dressing themselves. In severe tuberculosis of the leg absolute rest in bed is required. But with continued improvement the patient may be allowed to get up and move about, the joint being protected by a mechanical apparatus, which prevents its surfaces from coming in contact while walking, but allows active movements of the joint.

The tuberculous joint must be movable after the disease has healed. Bier says that a stiff joint, following healing of tuberculosis, is not a good result. The resection of a joint is, in regard to a cure, an illusion. It is followed perhaps by a healing of the tuberculosis, but not by a healing of the joint; it is a destruction of the joint—a mutilation.

*Read, by invitation, before the National Association for the Study and Prevention of Tuberculosis, at its third annual meeting, Washington, D. C., May 7, 1907.

It is true that the treatment of hyperemia has indeed a high purpose, namely: *the maintenance of mobility, an anatomical healing.*

Now, is it possible to restore the function of a joint in which the disease has progressed so far as to cause changes in the bone and cartilage with formation of multiple fistulæ? Yes, it is possible. We see at times cases of spontaneous healing of advanced tuberculosis. These observations show us the way, how best to proceed. We must assist the body in its own efforts at healing.

What can we accomplish by properly applied hyperemic treatment? The first sign is the abeyance of the pain, which is a certain proof of proper technique. Inflammatory contractures also soon disappear, and active as well as passive movements are again possible. We can convince ourselves of the movability of the joint without doing harm to it. The old teaching, viz., fixation of tuberculous joints, has been pushed aside by Bier. We believe that it is often not the tuberculosis which causes ankylosis, but rather the improper and overzealous treatment, which prohibits movements of the joint. It is evident that Bier has revolutionized the treatment of surgical tuberculosis.

Naturally, vigorous movements of the joint should be avoided, above all the "*brisement,*" all of which are contradictory to the teaching of Bier. Every excessive use of the joint should be avoided, as it leads to injury. The point is, to find through experience the "happy medium" between rest and action.

In the further course of the treatment we see other symptoms disappear: the swelling subsides, large fungous masses are transformed into hard connective tissue, which latter, by further hyperemic treatment, is also absorbed. Gradually, the contour of the bones again becomes distinctly visible. The clinical fact that mobility of the joint improves more and more, also that tuberculous fistulæ, even though they extend into the joint or bone focus, close, proves the healing power of the hyperemia.

But not always do these cases run such a favorable course. Often cold abscesses develop, and with their evacuation much necrotic tissue comes away. The better the technique, the less often these abscesses occur, and when they do occur they must be recognized early. We never treat them with injection of iodoform or other antiseptics. They are opened and treated with the cupping glasses, in the manner of which I shall speak later.

One must not think that the formation of a cold abscess indicates a turn to the worse in the course of the disease. According to Bier, it rather constitutes a process, by means of which the organism casts off the tissue incapable of healing. In any case one must not interrupt the treatment when a cold abscess does occur.

It is of greatest importance to emphasize the fact that the treatment of the tuberculosis by hyperemia occupies much time. He who wants to be healed quickly, must submit to resection or amputation. We calculate nine months or even longer for the healing of a severe affection of a joint; less involved cases heal more quickly. But it is known that treatment by fixation and by injection also requires much time, and is very often followed by ankylosis.

The treatment by hyperemia has a number of further advantages. It is very simple, and can soon be applied by the patient himself or by anyone who is in the house with him. In consequence of this we treat many patients in the ambulatorium. Advanced cases are attended for some time at the hospital; then they are allowed to go home, where they themselves continue the treatment. Every ordinarily intelligent patient soon learns to know when the band (Stauungsbinde) is properly applied. Patients who have been discharged are requested to come to the hospital every four weeks, where their technique is controlled and examination for cold abscesses is made.

One of our patients who suffered from a tuberculous knee with fistulæ, which had been submitted to resection with unfavorable result, and who also had tubercular fistulæ extending into the ankle joint of the other leg, effected a cure himself by proper application of the bandages. The tuberculosis in this case was so far advanced that amputation had been considered by us. A major operation was not done, however, on account of the fact that both legs were affected, a double amputation then being imperative. As stated before, the patient is now well.

Regarding indication, it is a noteworthy fact that almost all cases of joint tuberculosis in Bier's clinic are treated by hyperemia, and experience has shown that this treatment is applicable to almost all cases. It is to be regretted that tuberculosis of the hip joint cannot be treated in the same way. Many attempts have been followed by poor results, because of technical difficulties. Hyperemia of the shoulder joint, however, is practicable. I demonstrate here two methods of its application, the one by means of a ready-made ring, and the second by an improvised instrument of rubber tubing. It is worth mentioning that decubitus may quickly occur on account of our inability to change here the location of the constricting ring, and great care must be taken to avoid it.

Especially favorable results occur in tuberculosis of the ankle, elbow, and wrist. We have learned by a large experience that in these locations not only beginning and less advanced cases are curable, but such as formerly would have been resected or amputated. The severity of the disease is never a contraindication to treatment by means of hyperemia. Who would not rather undergo a year's treatment than lose a limb?

The old rule, that in people of advanced age amputation is the best treatment, we consider an unjust one, for in these cases the treatment by hyperemia is just as effective as in younger individuals. Of course, the same amount of patience and care is required.

By using hyperemia almost exclusively in the treatment of tuberculous joints, Bier is very seldom forced to do a resection; in fact, resections in his clinic have become very few in number. The operation is done when the general condition of the patient is very bad, when amyloid degeneration is present, or an additional widespread tuberculosis of the lungs.

It is to be regretted that the complicated construction of the knee joint does not permit of treatment by hyperemia alone; often one must question here whether a result equally as good would not be obtained in a shorter time by resection. Surely those cases in which subluxation of the leg has occurred, or ankylosis between patella and femur is present, are better treated, and in a shorter time, by resection. In such cases one cannot expect to obtain a movable joint.

In less severe cases the tuberculous knee requires, besides artificial hyperemia, the assistance of orthopedic treatment, namely extension and the application of splints during the time the patient is not in bed. Thus, the knee joint requires special treatment, as compared with other joints, which require only hyperemia.

The exudative form (hydrops) is never treated by hyperemia. There we adhere to the old teaching of using aspiration and injection of iodoform-emulsion. Thus, it appears that an exact diagnosis is primarily necessary in every instance. Of every diseased joint a radiograph is made. If a bone focus is found its presence in no way contraindicates the treatment by hyperemia.

In combination with the elastic band we frequently use the cupping glasses. This technique has been fully developed by Professor Klapp. I will now demonstrate them to you. We use them in all cases of beginning softening and of abscesses, which may or may not have fistulous openings. Here you see a large number of cupping glasses, which have various shapes, in order that they may be readily adapted to the different parts of the body. For most places the simple bell shape is readily applicable. Some have a U-shaped edge and are intended for convex surfaces, for example upon an extremity. Some have a special shape intended to retain the discharge and prevent its passing into the rubber tube. These large ones are intended to be used upon the female breast. This treatment is of great service and importance in puerperal mastitis.

The rarefaction of the air is accomplished in the smaller cups by a hollow rubber ball, in the larger ones by a pump. We allow these cups to remain in place three-quarters of an hour, but not without interruptions. They remain *in situ* five minutes; then follows a pause of about three minutes.

Also, when using the cupping glasses, the hyperemia must not be too intense. The glasses must be so applied that a *red* hyperemia, not a blue one, is obtained. In order that they may stay in place their edges are coated with vaseline, the same being applied to the surface around the fistulæ in order to avoid further infection. The application of the glasses is easily learned by the patient.

We open every abscess occurring in the progress of joint tuberculosis as well as in tuberculosis of soft parts, for instance in tuberculous lymphatic glands. We do this without fear of a mixed infection, because we know that the proper application of the cupping glasses prevents such an infection in almost every case. The two results obtained by proper use of the cupping glasses, namely hyperemia and discharge from the fistula, tend to avoid such a mixed infection. We succeed in evacuating daily through the fistulæ all detritus, however deeply it may be situated, and induce a hyperemia of the walls of the fistula and abscess cavity.

The result is that, after evacuating the detritus and pus, the discharge becomes serous, gradually becoming less and less, and finally heals. Every tamponade and drain is unnecessary, even harmful. There is no other treatment, which is so agreeable to the patient.

In all cases of open tuberculosis of joints we use, daily, both forms of hyperemia, the hyperemia band twice for one hour, and the cupping glasses forty-five minutes over the fistulæ.

Here is a simple apparatus in which (the principle being the same as in the cupping glass) the whole hand may be rendered hyperemic. The hand is introduced into the glass through a cuff, which is hermetically sealed by a rubber band. Now, we produce a hyperemia, which may be made very intense without harm to the extremity. Of course, it is also applied interruptedly. We treat in this manner the severe cases of tuberculosis of the hand, especially spina ventosa.

I could still mention a large number of other tuberculous affections in which hyperemia is applicable, for instance tuberculosis of the testis, for which trouble this method is a simple and excellent treatment, especially if both glands are involved and double castration would become necessary; further, tuberculosis of tendon-sheaths and serous membranes.

To recapitulate, it is very important to follow the treatment as practised by Bier. For this reason I have demonstrated it here. The hyperemia band must never cause pain or a sense of coldness. Bier's method produces in the diseased part an increased amount of blood, a slowing up of its current, but never a disturbance of nutrition due to a stagnation of blood.

I hope that my words will help to introduce Bier's treatment in America. I do not doubt that many advances in the technique will still be made and the renown of the method soon become widespread; for the treatment is agreeable for the patient and painless, and will, if carried out with the necessary patience, give results which cannot be obtained by any other treatment. Its goal is none other than that of healing without loss of function.

Bier, in the fifth edition of his book, "Hyperaemie als Heilmittel," has said: "Formerly I considered the hyperemic treatment of tuberculosis as good; now I consider it the best."

THE OPHTHALMOLOGICAL PHASE OF DISEASES OF THE ACCESSORY SINUSES OF THE NOSE.*

By Wm. CAMPBELL POSEY, M.D.,
PHILADELPHIA.

If the skull is submitted to a series of cross sections which expose the air spaces connected with the nose and its neighboring structures, it is easy to comprehend why inflammatory conditions in these spaces should excite ocular symptoms. Contiguity of tissue alone is cause enough to occasion them, but when one views the enormous extent of the mucous membrane which is spread out upon the walls of the sinuses and of the nose itself, and considers the numerous and intimate connections which this mass of loose vascular tissue has with the orbit and its contents, it is difficult to understand how an inflammation of any degree of severity could arise in a sinus without provoking changes in the eye and its adnexa. And, as a matter of fact, although the eye is in a measure protected by certain peculiarities of structure from participating in these inflammatory conditions, ocular manifestations are not infrequently occasioned by them, and these occur in so striking and significant a manner that the diagnosis of the intranasal condition may often be suspicioned by the ocular signs alone.

Just how these ocular symptoms arise is not always clear, for, owing to the absence of autopsy, the morbid anatomy of the region is as yet but little understood, but the prompt subsidence of many upon the removal of the intranasal conditions, in cases where the anatomical relationship reveals the origin of the affection, and in others where less intimate vascular and nervous connections are known to exist, demonstrates the dependency of the ocular inflammation upon that within the nose, and is evidence of the relationship between cause and effect.

Although cases which present ocular symptoms which are originated by nasal disease are not rare, in my opinion they are frequently overlooked, the

*Read at a meeting of the Ophthalmological Section of the New York Academy of Medicine, December 17, 1906.

etiology of the ocular affection being attributed to other conditions. This is accounted for chiefly by the sinusitis escaping detection, for the diagnosis of this condition is not easy, and repeated examinations by an expert rhinologist are often necessary before the inflammation in the sinus is discovered. It happens too often that the possibility of an ocular inflammation having originated in a sinusitis is dismissed by the patient's declaration that he has never had any trouble with his nose.

It has been thought, too, by many that pus must be present in a sinus to occasion symptoms in the eyes, though there is ample proof that a mere congestion of the sinus, without the presence of exudate, is sufficient to excite marked ocular symptoms. Thus, but a few weeks ago, a lady consulted me upon account of a very marked swelling of both upper lids which had come on over night. The lids were not reddened nor were the eyes otherwise inflamed, the swelling being occasioned by a puffiness of the lids without induration. An examination by her physician having proved the urine to be free from albumin, she was asked to consult her rhinologist, Dr. George C. Stout, who found marked congestion of the anterior ethmoidal cells, but repeated catheterization failed to reveal pus. The treatment of the intranasal condition was followed by a rapid subsidence in the edematous swelling of the lids.

I have long been interested in the ocular symptoms which diseases of the accessory sinuses of the nose may occasion, and have already contributed several papers upon it. In the last communication, which was embodied in a paper before the Section on Ophthalmology of the American Medical Association at Portland, Oregon, I endeavored as far as it was possible in the light of the present knowledge of the subject to perfect a symptomatology in this class of cases, the clinical notes and observations of the cases upon which the paper was based having been presented before the Ophthalmological Society of Baltimore some time previously. As these papers have already been published, and may perhaps have been read by the gentlemen present, it is unnecessary to refer to them now, though I wish to state that the continuous observation of many cases in both private and hospital practice during the eighteen months which have intervened has served still further to confirm me in the views he then expressed. During this period I have had opportunity to observe, particularly, other cases of moderate inflammation of the optic nerve complicating ethmoiditis and sphenoiditis which had been occasioned by bathing in cold salt water.

In this class of cases the nerve, although protected from the sinus by its sheath and by the double layer of periosteum which covers the bone forming the barrier between the nerve and the sinus, becomes affected by contiguity of tissue, the inflammation varying in intensity from a simple edema to an active retrobulbar inflammation. Moderate degrees of neuritis present but slight ophthalmoscopic signs, but may frequently be diagnosed by the distention of the lymph sheaths of the retinal vessels, and objectively by a diminution in the light sense, which may be conveniently tested by Bjerrum type. In this class of cases there is often a feeling of fullness in the eye, with some pain on rotation and attempts at pushing the globe back into the orbit, the symptomatology, in fine, of cases of so-called "optic neuritis from rheumatism." Indeed, it is probable that if more cases of this type were subjected to a careful rhinological examination a sinusitis would be found to be the underlying cause in many.

I have not been able to convince myself of the changes in the field of vision which occur in cases of sinusitis without ophthalmoscopic signs, which Ziehm and Kuhnt attributed to a nasal condition, and suspicions that the contraction and scotomata which were observed by these authors were due to neurasthenia or intercurrent causes. Naturally, scotoma and limitation of the field are to be expected where there is ophthalmoscopic evidence of neuritis.

Although perhaps it is a trite observation, I desire to emphasize the frequency with which edema of the lids is encountered even in beginning cases of sinusitis. The puffiness is usually most marked in the upper lid, and particularly on the nasal side, though the entire lid may be swollen. This edema is to be distinguished from the inflammatory swelling and thickness of the lid which results from cellulitis, as it is entirely noninflammatory in origin, as well as in appearance, and also from the ptosis which is at times present as a result of a palsy of the levator of the lid. The swelling is usually most marked in the mornings and disappears during the day, but it is also apt to be brought on by bending the head forward. Like all other ocular symptoms of sinusitis, the edema may disappear for a time, with the discharge of secretion from the sinus, but reappears when the fluid reaccumulates and the congestion of the mucous membrane becomes greater.

That affections of the muscles of the eye are not infrequently the result of sinusitis is occasioned by the juxtaposition of some of them, like the internal and superior rectus, to the walls of the orbit, and by the very close association of the motor nerves supplying the muscles with the sphenoid cavity, as they pass along the outer wall of the sinus.

As in many of these cases, the function of the muscle is but slightly interfered with, double vision is complained of but rarely, and diplopia can be detected only by careful search in the periphery of the field. It should be remembered, however, that actual palsy of a muscle is not necessary to occasion diplopia, but that double vision may result from even a slight displacement of the globe by exudation or by the distended wall of the sinus. If the encroachment by the wall of the sinus or its exudate be gradual, as a result of chronic empyematous conditions, diplopia rarely occurs, as the visual axes have opportunity to adapt themselves in a measure to the changed conditions under which they are forced to operate. Marked muscular insufficiencies not infrequently arise in this class of cases, hyperphoria and exophoria of varying degrees being the conditions generally originated by them, hyperphoria, of course, being induced by a swelling in the floor or the roof of the orbit, exophoria by some disturbance in the inner wall.

As an example of an exophoria excited by an ethmoiditis may be cited the case of Mrs. W. T. F., who is under treatment at the present time. This patient, age 38, came complaining in general of a sense of confusion and head pain, which was increased by attempts at reading or exposure to bright lights. There was no dizziness or diplopia. These symptoms had extended over a period of two years and followed a severe attack of grippe at that time, the grippe having apparently attacked the head, causing nasal obstruction and a general sense of head fullness. Examination showed an apparent very marked broadening of the root of the nose; both eyes deviated perceptibly outwards under cover, and adduction was practically absent. Exophoria at 5 meters equaled 15° and there was a left hyperphoria of 2°. The fundi were normal. There was moderate hypermetrpic astigmatism in both eyes.

Upon account of the nasal and head symptoms, and the marked broadening of the base of the nose, the patient was referred to Dr. Packard for a rhinological examination. Dr. Packard reported that the right nostril was almost completely blocked by a mass of polypi which presented streaks of pus on their surface, while there was considerable hypertrophy of the middle and lower turbinates on the left side.

Being convinced that the ocular symptoms were probably secondary to the nasal, sphero-cylindrical glasses with weak prisms, bases in, were ordered for temporary use, and Dr. Packard was requested to relieve the intranasal condition at once. He accordingly snared off two very large polypi from the right naris, which procedure was followed by a gush of fetid pus. The discharge proved to come from the ethmoid, from which a large shell of dead bone was removed by the forceps. A small polypus was subsequently removed from the left naris.

Both Dr. Packard and myself are of the opinion that at the time of the grippe, two years ago, there was an ethmoiditis, which resulted in the closure of the orifice of that sinus, and that as a consequence of the retention of exudation from the mucous membrane, the walls of the cavity became distended, and encroaching upon the orbit gave rise to the divergence of the visual axes. Later necrosis of the walls of the sinus followed, with partial discharge of the contents of the cavity into the nose, with the development of the polypi. Since the operation, which was performed about two weeks ago, the head symptoms have been relieved, though the ocular condition is naturally unchanged.

Another class of cases which may be excited by a sinusitis, and which are of great interest to the ophthalmologist, are those designated as "prelacrymal abscesses," referring by this term to the swelling which forms at times above the internal palpebral ligament, and somewhat external to the lacrymal sac. While its position serves to differentiate it readily from abscesses of the sac itself, it is frequently mistaken for that condition, and Bowman's operation is performed. In many of these cases, as is well known, the abscess results from a necrosis of the lacrymo-ethmoidal cells, in others it marks the point of suppuration of the frontal cells, which frequently have an anomalous distribution. Abscesses of deeper parts of the orbit may point in this region, the purulent matter gravitating into the neighborhood of the sac by the peculiarity of the insertion of the fascia.

Though the differential diagnosis in these cases of prelacrymal abscesses is usually comparatively simple, at times the pus gravitates behind the sac in such a way that the exit to it is closed, and an ectasia of the sac itself occurs, with all the signs of true lacrymal abscess. Incision by means of the Bowman procedure does not, however, liberate any pus, the purulent matter escaping only after the probe is withdrawn and passed horizontally into the cells forming the inner orbital wall.

I have encountered a number of such cases and have been compelled to resort to extensive incision and drainage in place of the simple dilatation which I had planned. Within the past few weeks I have operated upon an old lady who presented the appearance typical of simple mucocele of the sac. The quite pronounced swelling which was present was in the classic position, and when the finger was applied the contents apparently steadily emptied themselves into the nose, for there was no regurgitation into the conjunctival cul-de-sac. Her physician, who was somewhat of a throat and nose specialist, had pronounced her nose free from disease, though the turbinates were noted as being swollen. The sac was incised by the ordinary Bowman procedure, but without avail, no pus escaping until a deeper incision was made into the tissues back of the sac, when a large quantity of pus escaped from the lacrymo-ethmoidal cells, which were found, upon probing, to be extensively diseased.

Peters described similar cases in 1902 in *Die Zeitschrift für Augenheilkunde,* which he had found to originate in empyemas of the frontal and ethmoidal cells and in rare instances in a maxillary periostitis excited by carious teeth.

It is unnecessary before this audience to dwell upon the frequency with which orbital cellulitis is occasioned by an inflammation of some one of the accessory sinuses, and to refer to the dangers which threaten the eye under such conditions. Although the sinus at fault can usually be detected prior to the operation, the rhinological examination at times does not reveal the seat of the disease, and the establishment of the diagnosis is deferred until incision is made into the orbit. Even then, however, in a certain proportion of cases, there will be disappointment at the nonappearance of pus and the impossibility of detecting any necrosed bone in the walls of the sinus, though it should be remembered that a sinusitis may occasion an orbital cellulitis of marked intensity without the bone forming the barrier between the sinus and orbit being diseased, the inflammation spreading from the sinus to the orbit by the vascular channels which normally exist in the wall of the sinus. The necessity for the correct diagnosis and treatment in this class of cases is apparent, for not only may the eye be saved by proper surgical means but life itself.

Finally, as an unusual condition which appeared to be dependent upon a nasal condition, I would refer very briefly to the case of a man by whom I was consulted a few days ago upon account of "a blind spot which appeared in the center of the sight of the left eye," as he expressed it, whenever there was a high wind and freezing weather. He said that he was always free from the spot in summer, but that it had recurred for three winters following a heavy cold which he had contracted in St. Petersburg three years before. The spot was black, except at its center, which appeared bright and luminous, and usually faded away after the patient had been in warm air for some time.

It was elicited that he was troubled but little with his nose, except that the nares would close alternately upon slight provocation. Examination revealed that both eyes were normal (the cornea was examined carefully under high magnification to exclude the epithelial haze which I think Mr. Nettleship has recorded as arising from exposure to high wind) save for a small spot of apparently old choroiditis in his left eye. No scotoma could be outlined by the visual field, though there was a perceptible enlargement of the blind spot. Corrected vision was normal in both eyes. Being curious to know if there was any connection between the ocular and the nasal condition, the patient was sent to Dr. Packard, who reported: "Mr. T. H. G. has a great deal of hypertrophic rhinitis, but no sinus trouble or pus center anywhere around his nose. I think there is no doubt that his nose becomes very much occluded in cold weather, because the erectile tissue in his turbinates is extremely sensitive, and swelled even under the ordinary routine examination."

In conclusion, I believe that while there may be a tendency upon the part of some to exaggerate the

connection of ocular conditions with sinusitis, and while there is the temptation for all to discover causes which they are interested in finding, in agencies which may not be implicated in any way with the disease within the eye, careful rhinological examinations should be made in all suspected cases, and the possibility of the ocular affection being occasioned by the nasal only dismissed when repeated examinations have failed to discover any disease within the cells.

RELATIONS OF EYE TO NOSE, WITH CERTAIN GENERAL CONSIDERATIONS.*

By COLMAN W. CUTLER, M.D.,
NEW YORK.

It is the purpose of this paper to give a brief summary of the ocular conditions and symptoms, chiefly of a functional nature, which seem in many cases to be associated with or dependent on obstructions of the nose and diseases of the neighboring structures. Allusion will be made to the examples of intraocular diseases which have been reported by numerous observers, some of which need further substantiation.

The extension of purulent inflammation from the nose or from the ethmoid cells or sinuses of the frontal or sphenoid bones, with pressure upon the nerve or with displacement of the eyeball is familiar to all, and the literature has reached large proportions. A review of the subject by Eversbusch (Graefe-Saemisch, "Handbuch der Augenhilkunde," second edition) shows the futility of attempting to add to the stock of knowledge from a limited personal experience.

The association claimed by certain writers to exist between inflammation of the nose and especially of the sinuses, not necessarily purulent, and certain intraocular inflammations such as uveitis, the etiology of which is often obscure, is of great interest. If such an association is proven to exist, information regarding it will be welcomed, for many of those cases of uveal inflammation have proven resistant to treatment, and have eluded all attempts to fix their direct cause. The question is by no means a simple one, for the mere coincidence of nose and eye trouble does not prove an etiological relation. The disappearance of the one following the successful treatment of the other would be, however, strong evidence, and when a sufficient number of cases have been reported our knowledge of intraocular inflammation will be materially increased. I have not seen such an association in my own practice. A careful examination of the nose has been made in cases of uveitis, glaucoma, and detachment of the retina, in which the cause was obscure, and I have yet to see a case in which the ocular condition could be said to depend directly on disease of nose or sinuses.

Dr. Posey has reviewed this whole subject so fairly that it is hardly necessary to dwell at length on the statements of Kuhnt, Ziehm, Fish, and others, whose views have not met with general acceptance. Moreover, the frequency of empyema of the sinuses without ocular complications makes it highly improbable that a hypothetical mucocele of the frontal sinus could be the cause of severe intraocular trouble—but this has recently been urged so insistently that we must give it fair consideration.

In spite of Dr. Fish's case of detachment which disappeared after washing out the frontal sinus, one remains sceptical; not more so, however, than as to the efficacy of the usual method of treatment in such cases, since rest in the recumbent position, pressure bandage, and pilocarpine offer small hope for a cure in most cases, while subconjunctival injections of salt solution and puncture of the sclera are equally uncertain.

In looking back at several cases of acute uveitis, frontal pain and nasal obstructions were not prominent symptoms, but in three cases, which yielded promptly to large doses of sodium salicylate, hot compresses, and atropine, the nasal or sinus condition, which may have been a contributory cause, would have been favorably influenced by the treatment. It is not fair, therefore, to exclude this association until we know more of the relationship than we do at present, and it is important that specialists familiar with the technique of nasal and sinus examinations should be consulted in all doubtful cases.

The very intricate circulatory and nerve relations are well described by Eversbusch and Ernst Winckler, among many who have studied the subject, and their significance in this connection is apparent to all, in relation not only to infection, but to passive hyperemia, and as a basis of various nervous conditions called reflex. After describing the normal relations of veins and lymphatics, Winckler mentions certain anomalies, of which there are many, and says: "In any case where disease of the eye certainly depends on nasal obstruction, there must be abnormal relations, or else the latter would be followed much more often by ocular diseases." Kuhnt, Winckler, Posey, and others have seen a hyperemia of the nerves with tortuous vessels on the same side as the empyema. Kuhnt states that this is a very frequent accompaniment of both acute and chronic processes, and is congestive and not inflammatory. This passive hyperemia is, according to Ziehm and Kuhnt, an important predisposing influence for the different forms of intraocular inflammation. It is common to find hyperemia of the conjunctiva, photophobia, and asthenopia in cases with a congested nasal mucous membrane, with contact of turbinal and septum, and it is possible that this condition may also predispose the eye to infection. Randolph has shown that some lesion is needed before certain toxins can obtain a foothold on the conjunctiva, and the same may be true of the uvea.

Kuhnt mentions several cases of hypertrophic rhinitis with empyema, in which there were opacities in the anterior part of the vitreous and postcortical cataract. He also saw three cases of thrombosis of the central vein of the retina on the same side with the empyema, in which there was absolutely no other cause assignable.

Many cases of the most diverse nature have been reported by these and other observers, but in proportion to the frequency of nasal and sinus disease those with intraocular inflammation or with organic changes in the eye, must still be regarded as exceptional, and due, as Winckler has said, to exceptional conditions, such as anomalous arrangement of vessels or lymphatics. Some cases are part of a general septicemia, in which the empyema is the starting point, or, more frequently, both eye and nose are affected by a common cause, as in influenza; others, called functional, have as a basis the nervous temperament, which makes one person suffer intensely from a fault or error which others endure with little or no discomfort. These are the most frequent, and they are especially elusive, because the ocular symptoms are frequently out of proportion to the underlying cause.

It is not easy to analyze these functional conditions or to classify them: some may be due to obstructed inspiration by which the suction which tends to

*Read in abstract before the Ophthalmological Section of the New York Academy of Medicine, December 17, 1906.

empty the vascular tissues of the nose is hindered. Ziehm has stated that this suction is ten times less in mouth breathing than in the normal conditions. Kniess and Zarinko ascribe these ocular symptoms to reflex irritability from the nasal mucosa, and Zarinko (Eversbusch, p. 63) denies Ziehm's theory on apparently well-grounded physiological facts. Whatever the mechanism, hyperemia in the nose is a direct cause of congestion in the orbit, lids, conjunctiva, and probably in the intraocular structures as well. This is a sufficient cause for asthenopia.

It will be interesting in this connection to quote from papers by Dr. Haskell of Boston the results of his careful clinical observations, which deserve our consideration.

"The nasal factor, usually a contact . . . . was not always suspected at first; 65 cases were observed; headache was the most constant symptom, occurring at night, or on waking, and relieved by a change of position or any measure which lessened the congestion in the nose. Asthenopia and pain independently of the use of the eyes was frequent. A striking symptom was present in a number of cases—a feeling of confusion and helplessness on attempting any mental exertion, increased by the use of the eyes, but not dependent on it."

A symptom pointing to the nose, and on which Dr. Haskell lays stress, was a variable error of refraction, which made it necessary to change glasses frequently; after the relief of the nasal condition the refraction became stable, the axes of the astigmatism tended to become more symmetrical, and glasses were worn with comfort. It is not necessary to give the details of the 42 cases in which these signs of irritability of the ciliary muscles were noted. We have seen such conditions in many kinds of nervousness, and the salient point is that the nose may be an unsuspected source of trouble.

Of the 65 cases, 8 per cent. were reported normal; 92 per cent. faulty as to the nose; some form of pressure contact was found in 85 per cent. of all cases; 38 were operated upon, and among these there was no relief in three cases, partial relief in 19 cases, entire relief in 16 cases.

In this nervous, high-strung age of overwork and bad hygiene, it is important to consider, first of all, the personality of the patient and his environment and the manner in which he works. It is not possible to obtain ideal conditions, but only after this has been considered and the refraction most carefully corrected, and when variable, under atropine, are we justified in subjecting the patient to prolonged treatment of the nose or sinuses for functional disturbances of vision.

One regards with some compunction the attitude of the general practitioner and that of the patient himself, in the face of this uncertainty. It would be of great value to formulate some general rules by which the cases of disordered ocular functions, or pain in the region of the eyes, might be classed as of ocular or extraocular origin, but unfortunately the question is not a simple one. Dr. Haskell states that headache or asthenopia, which does not follow the use of the eyes, cannot be relieved by glasses. While this may be true in a general way, there are certainly many exceptions, and as the eyes are in constant use, refractive errors are always a potential cause of the symptoms described. On the other hand, when the nose is the immediate or active source of trouble, glasses which should be worn may not be tolerated until that is relieved. It is easier for the patient and more natural when the ocular discomfort is prominent, to submit to an ocular examination before entering on a more or less formidable course of treatment for nasal or sinus diseases, and in those cases in which refraction is variable, atropine, especially in children and young adults, should be used, not only for the added certainty it gives in determining the error, but for its therapeutic effects as a sedative, and the frequent relief may be due, not only to the physiological rest which it gives to the eyes, but to its effects on the nasal mucous membrane.

Unquestionably, every case must be studied individually, and much valuable information can be obtained by a careful history of the persistence of the symptoms, and their coincidence with signs of neighboring trouble, and of equal, if not greater importance may be mentioned the study of the general health. Leaving out of consideration the nasal obstruction and purulent cases of sinus diseases, and the obvious eyestrain, which no competent specialist will overlook, it is not too much to say that functional trouble has been suggested in many a nervous patient whose varying and often contradictory symptoms might better have been reached from a broader standpoint.

It is unfortunate that such confusion exists as to the pathogeny of many of these cases of nasal and ocular trouble. The coincidence of symptoms proves either that one depends on the other or that there is a common cause. In cases of actual infection of sinuses, or of such interference with functions in the nose as to make it a cause of serious discomfort, the indication for more or less radical treatment is clear, and very often the condition of the eyes will be improved thereby. Cases of that sort are too numerous to require citation, but are there not as many in which the apparent association has been disproven by failure to relieve the symptoms after painful and prolonged local treatment?

I would not venture to criticise the work of the rhinologist—perhaps he might retaliate by caustic allusion to the indiscriminate giving of glasses for small errors of refraction. Certainly, we have been open to criticism on the question of muscles. But behind and above all of the persistent functional disorders of the eyes and of the nose, as well as of digestion, circulation, in fact the disorders of the entire organism, which cannot be attributed to some obvious fault, is the nervous control, and this must be reached in the last appeal by hygiene, which means adaptation of means to ends.

Many, perhaps most of our functional errors, are failures of the organism to adapt itself to increasing and unreasonable demands. The numerous cases, so brilliantly outlined by Dr. Gould, are instances of the failure of those physically frail to meet the imperious demands of a superabundant mental energy. No doubt glasses would have helped very materially in many cases to relieve the stress; possibly also there were nasal conditions which might have been relieved, but it is not reactionary to state that most of the great men would have suffered their crises of nerves, the labor pains of genius, in spite of all the modern tinkering which could be devised.

It is our duty, of course, to correct every fault in sight when the symptoms demand it, but a conscientious specialist who is not an egotist must feel at times that, although his glasses have relieved the symptoms or the breathing is freer after nasal treatment and the patient's head is clearer, he has not struck at the root of the question. The patient should not have been susceptible to such small faults, and at times it comes home to the physician—not always to the one who flattered himself that he relieved the symptoms—that the underlying trouble,

the failure in adaptation, is cropping out in some other way quite as serious, and that the remedy is to be sought in a broader and more fundamental regulation of the mode of life. There is an admirable book, the "Psychic Treatment of Nervous Disorders," by Dubois, which should be read by all physicians who seek this judicial standpoint. The specialist, without sacrificing in the least his concentration or the confidence in his ability to help those who belong properly in his category, may, it seems to me, increase his usefulness, and will certainly add to his own intellectual satisfaction if he accepts the broader point of view.

Many of our patients who are distressed by small errors of refraction, or who complain of asthenopia without discoverable cause, or who have a too ready reflex irritability, may be called neuropathic, and these words of Dubois seem most appropriate at the present time: "Whoever wishes to treat neuropaths must first of all be a good clinician, in order to recognize the numerous organic troubles and to assign them their place; but he must also be a psychologist and moralist, in order to completely modify the mentality of his patient."

52 West Fifty-third Street.

EVOLUTION OF LIFE FROM THE LIFELESS.

By JONATHAN WRIGHT, M.D.,

NEW YORK.

I have had occasion to refer in another publication[1] to the lifelong heresy of Dr. H. Charlton Bastian. He has now published another book on the subject of Archebiosis.[2] The recent recrudescence of interest in the theory of spontaneous generation has furnished him with a kindlier sentiment than prevailed thirty years ago, when his victorious opponents were Pasteur and Tyndall. Jacques Loeb has declared his belief in the possibility of the artificial creation of life, and Le Dantec[3] has voiced the sentiment of many others in asserting that no one would be surprised if the actuality of spontaneous generation were demonstrated to-morrow.

Considering the fact that for thirty years the question has been entirely banished from the realms of scientific discussion, this revival of a discarded and discredited theory may possess sufficient interest to warrant me in again referring to the subject here.

It is true that the majority of biologists still regard the discussion as fruitless. Indeed not the slightest direct experimental proof has been attempted, except by Dr. Bastian. It might be thought that the interest in the subject had revived from a calmer survey of the grounds upon which Huxley pronounced the idea a chimera. While it is quite apparent that these were insufficient for his sweeping generalization, it is not the fallacy in the deductions from the work of Pasteur and Tyndall the realization of which has reawakened the ancient belief. The creators of modern bacteriology demonstrated that they indeed could render culture media sterile without destroying its nutrient qualities, but it by no means followed that they thereby demonstrated the impossibility of life appearing in those media not rendered unfit for life by the disintegrating action of heat and other measures.

We all now realize that in destroying life in broth or in other fluid, we very possibly also destroy in it the potentiality of producing life. It seems very likely that while an environment *must* be able to maintain life if it is able to start it, it *may* be able to maintain life without being able to start it. In the predilection of mankind for cooked food we receive a hint of the possibility of an underlying law, *i.e.* a thing is more readily worked up into food for existing life when it is deprived of the higher potentialities which might produce life.

But, as I have said, these considerations have had no effect in awakening new interest in an old doctrine. The causes for this are to be found in a readjustment of ideas which have arisen from facts brought to light in other fields of scientific activity. Darwinism was still imperfectly apprehended in general scientific circles at the rise of modern bacteriology. It seemed to simplify the question of the appearance of life by removing it to a remote geological period, or even by pushing it off the earth altogether. Lord Kelvin, it has been pointed out, has displaced but not dismissed the question by supposing that life came to this planet from another, riding on a meteor. Darwinism has not simplified the matter, but, on the other hand, it has rendered it more pressing by inculcating a necessity for a conception of a continuity in natural phenomena, as conceived by thinking men, which at first was but dimly apparent, and even that in biology alone. Gradually, especially of later years, the despair of taxonomists at their inability to fix a limit to any related forms of life, to divide them into species, has been of the same pedagogical stripe of discouragement as that exhibited by those attempting in vain to define and fix a limit to life itself.

The trend of physical as of biological science in its broadest outline is towards the connotation of the existence of an absolute and uninterrupted continuity in all processes open to the apprehension of the senses and understanding of man. This belief, existent from the dawn of philosophy, received a more convincing confirmation in the life work of Francis Darwin than in any of the other epoch-making activities of the Princes of Science.

The discovery of the phenomena associated with the radioactivity of matter, spectrum analysis applied to the light of the blazing stars, the necessity of conceiving of smaller aggregates of matter than the atom and the mathematical demonstration of their existence by Professor Thomson, "the man who split the atom," the extension of the idea of Natural Selection to the birth of atoms and of worlds, are among the currents of thought which have carried us on to a realization of the absolute nature of this continuity of phenomena from the primordial whirlpool of energy in the ether up to the most complex molecule of protoplasm in the organic ferments. To stop short there without pitching forward beyond is almost an impossibility for the human intellect.

Elsewhere,[4] in speaking of the colloids, I have taken note of one line of biological investigation which has led up to the subject in hand along paths of the most painstaking and laborious objective experiment and of the most ingenious and careful observation. Let us turn to another.

The origin of the analogy drawn between the formation and growth of a crystal and life has been traced back to Maupertius, that "flower of human thinkers," whom the great Frederick petted and persecuted, at whom Voltaire jeered, whom Carlyle, the false prophet, consigned to oblivion, though "honest and of high talent." The discoverers of the cell structure of living things called to mind the same analogy, and on it Herbert Spencer founded his far-reaching biological theories. It has been left to the last few years to give a deeper meaning to these vague analogies and the study of the liquid

cells by Lippman, Lehmann,[5] Le Duc, Herrera,[6] and others has confounded those disposed to remind us that analogies are apt to lead us into error, as indeed they are; but nevertheless they have their value. Ostwald, one of the greatest of living chemists, believes crystallization is the process actually at work in the living cell, while Krompechner[7] goes so far as to see and figure tetrahedral and hexahedral crystal forms in the changes the nuclei of the cells undergo during division. We are here reminded of a passage in the second part of Goethe's "Faust," where Wagner in his medieval laboratory is toiling to create life. Peering into his flaming flask he mutters:

"The mystery which for man in Nature lies
We dare to test, by knowledge led;
And that which she was wont to organize
We crystallize instead."

Mephistopheles utters the same jest which still has its sting for the orthodox:

"Who lives learns many secrets to unravel;
For him upon this earth there's nothing new can be;
I've seen already in my years of travel
Much crystallized humanity."

In the crystal men have long recognized some internal power which enables it to grow by accretions from its environment as does the living cell, but under more exacting conditions. At first this was supposed to occur by adsorption alone, and not by intussusception, that is, by layers on its external planes and angles, and not by internal digestion, but it has become plain from the popular demonstrations of Le Duc and others, to which I have referred, that the so-called liquid crystal, like the colloid cell, can be made to exhibit currents of intake and outgo, endosmosis and exosmosis, and even show many changes of internal structure resembling the processes of the nucleus, which these artificial cells also possess, in proliferation and division. These things have become more or less familiar to the general reader in magazine reviews. Though these crystals, at least some of them, show the characteristic action on polarized light, many, even Le Dantec, say it is a play on words to put them into the same category with quartz and ice-forms, with which we are all familiar.

Some of the rigid crystals present one striking analogy in particular to animals. If they have their angles chipped off or their planes fractured by a loss of substance, like the crab which has lost its claw, they will regenerate or repair the loss. They were supposed to do this only in a supersaturated solution by accretion or adsorption directly to the injured spot, differing thus from animals which will do it, while fasting, out of their own substance. Lehmann and Przibram have gone over the various analogies that crystals have with living things.

To single out one of them, it now appears[8] that, like the crab with his claw, the crystal also repairs its injuries when starving. Hung, in other words, in an exactly saturated solution, where it will not grow in weight, shielded from the evaporation of the mother liquor, the angles and planes of the tetrahedral or octohedral will readjust themselves in such a way as to heal the wound and eventually a perfect crystal, characteristic of its mother liquor, will result. This, it is argued, as with living things, can only occur from intussusception. Thus the polarity of growth is apparently of the same internal nature for crystal as for crab. This power of regeneration is not inherent in all crystals, nor in all living things, but it must be noted that among the simplest unicellular forms of life it is most persistent and most frequent. For many years it was claimed that crystals can only arise in the saturated solutions of certain salts, in which there is a pre-existing crystal, just as it is orthodox now to declare with Verworn that "living substance arises only where living substance has been," but it is now certain that crystallization may occur spontaneously.

Is there then some mysterious vital force at work within the crystal, or is there no "vital force" within the living being, or is all this mere "analogy?" Around this question, vital indeed, the battle is raging. These analogies, which I have only touched upon, are very numerous between colloids and crystals and "life." A neovitalist can scarcely formulate a law for living things to follow, but it is found on analysis to rest on physical principles as applicable to the dead as to the living. Occasionally even yet someone defines life as motion. A drop of quicksilver will roll about, they will admit, and will retain its form, but it will not send out pseudopodia and creep about like the ameba or the tiger in search of prey. The drop of quicksilver will not do this, it is true, but the creeping liquid crystals of Lehmann will do it, and on analysis, noting the change of form, it is found to be due to alteration of the surface tension, brought about by the environment acting on internal forces. In fact the same thing which holds the drop of oil to its globular form on water causes the colloid cell and the liquid crystal to move. They are simply apparently so synthetized that they react more readily to the influence of their environment than does the quicksilver and the oil in water. They must all of them find the proper environment in which they are fit to survive, just as Boussinesq supposed for the universe itself. The mercury is an element, the oil a high compound, the liquid crystal and the colloid still higher aggregates, and the ameba is the "colloid of colloids," but the same electrodynamic forces give them their relation to their environment. Adaptation to that environment is the rule to which the ameba, the nations, and the individual man and the crouching tiger must conform or perish. There can be no question that this similarity of states, this analogy of the active phenomena of inorganic matter and of protoplasm, has been an important aid in forging the bond of continuity existing in men's thoughts as to the fundamental identity of the living and the lifeless.

Crude as is this sketch, unconvincing as it would be were it not possible to pad it out with details of observations and experiments that would fill thousands of these pages, we plainly perceive from it that it is on this account, and not on account of the realization of the fallacies of Huxley's and Tyndall's arguments, that we are on the lookout for demonstrations of the line where the lifeless becomes alive.

Bastian, overwhelmed thirty years ago, after almost a generation of fruitful work in which he has made his name a familiar one in neurology, returns to the charge at a more opportune moment, and with dauntless courage and tenacity reiterates his convictions. In Science, however, admiration for honesty and courage must not blind us as to the path which leads toward the truth. "*Unus contra mundum*" may be a heroic sort of legend, but it is as often floating over the Castle of Error as over the Stronghold of Truth.

One of Bastian's plausible *a priori* arguments for an ever-present Archebiosis is that organic matter in solution, that is, the more complex forms of matter, those molecules of unstable equilibrium, is now much more widespread over the earth than in the early days of terrestrial life, and therefore the opportunities for life to appear *de novo* are more frequent. For reasons to which I have alluded, we are driven to the conclusion that if spontaneous gen-

eration is going on now it must be doing so among the low forms of life already existent. In life already in existence we must presuppose an acquired power of adaptation, which exists even in the inorganic colloids, a resistance to destructive forces, *viability* to a degree which nascent life cannot possess. Verworn indeed, and much later Burke conjectured, as indeed do Weismann and Benedikt, that there are or were half-way combinations, biogens or biophors or protoplasmic flakes not yet risen to the dignity of life.

Pflüger many years ago, and, more recently and vaguely, Burke have imagined a state of incandescence as necessary for their formation. But cyanogen, the supposed radicle of Pflüger, is not existent in all the forms of life; it may be formed in such incandescence as still occurs on the surface of the earth, the lightning, volcanoes, etc., and indeed this idea, of the physical causes of life not being now with us, is of late years little heard of.

However all this may be, doubtless there are chemical compounds preexistent, upon which the new birth of life depends. Manifestly as we have insisted, whenever it occurs conditions must be fit at the same time and place, not only for the birth, but for the survival of life. We have seen that the application of a sufficient degree of heat will certainly kill all preexisting germs. Now even Bastian admits that if we raise the temperature sufficiently high, above 150° or 160° C., his germs do not appear in even his so-called generative fluids, but the latter, whose ingredients it is not here necessary to discuss, when heated to a lower degree, or not so frequently, he supposes to retain the potentiality of generating life after all life in them has been destroyed.

We well know from observation and experiment that there are forms of life so minute that a glass magnifying more than a thousand diameters cannot reveal their existence, but we also know we can destroy this infra-microscopic life in the same way we destroy other germs. Is it reasonable to suppose that the nascent molecule, about to assume the properties of life in Bastian's tubes, if such there were, would not break down under the heat?

Can we agree with him when he asserts that his experiments demonstrate the reappearance of life in his flasks after heat has destroyed the life which has existed there before it was applied? Is it possible that the swirling molecules of these colloids have secured an equilibrium which is not broken up by heat when the bacteria with an acquired resistance, an adaptation to their environment, have been unable to continue their existence?

When that equilibrium within the nascent colloid is first established, when it first becomes "instinct with life," as Bastian's experiments seem to show it does, with only such an heredity behind it as it has brought over from the inorganic state, it is natural to suppose it very unstable. It must lack, like the growing crystal, a stability in the environment which heat, violently affecting the molecules of matter, would destroy. The living thing which we know in daily life has evidently acquired, through a long line of ancestry, that tenacity of life necessary for existence, not primordially inherent in the speck of protoplasm from which Huxley supposed it sprang. In the sequence of cosmic events it has widened its field of adaptation. This sequence of events, we have seen good reason to suppose, stretches far back of the appearance of life for its beginnings. Can we believe that at the point where the lifeless becomes alive suddenly such combinations assume a stability greater than they subsequently possess, that they resist a degree of heat which destroys the salamander itself? Once born Bastian admits they may be destroyed at the boiling point of water.

All *a priori* argument is indeed in favor of the theory of an ever-present spontaneous generation in conditions suitable for the maintenance of life, and thus, in this twentieth century, the theory finds a receptive audience of which it was deprived by Pasteur and Tyndall, but I think we find, on a careful analysis of Dr. Bastian's conception of how and where it occurs, that the *a priori* argument deserts him. In the very terms of the problem there seems an insuperable difficulty of demonstration as Bastian proposes to solve it.

I have had occasion to refer to Dr. Bastian's work on Heterogenesis, and, while disposed to take the most liberal view of the mutability of the lowest forms of life, a view which modern researches in bacteriology are constantly strengthening, I have pointed out that many of Bastian's observations are entirely irreconcilable with the *a priori* arguments which he brings forward to support the probability of the occurrence of spontaneous generation. So here in his more recent book we may note the same incongruity in the argument.

But Dr. Bastian does not take his stand on the general principles alone for which he would find much support. He makes no final appeal to plausibility. He, as well as the rest of us, knows full well that modern science has little to say to plausible theories or *a priori* arguments, or the analogies such as I have traced in this and other papers. Dr. Bastian stands firmly on the experimental evidence which he advances. Nevertheless, his argument being defective, we could not on these grounds alone suppress incredulity of his results. We may well scan the methods of his experimental demonstrations. This is no place to go into such technical matters. It seems to me that for very many of his demonstrations he will not excite sufficient interest in scientific circles to secure their repetition by others. Bacteriological work of thirty years has destroyed their value. There are some of his experiments, however, which seem without a flaw in their plan, and as Dr. Bastian has only to demonstrate one condition or set of conditions under which spontaneous generation may occur, in order to prove the probability of its occurrence under others as yet impossible for man to devise, so far as I can see there is no way of refuting them, but by their repetition and the demonstration of errors of technique which he may have committed.

Dusty Books.—Sir Lauder Brunton, in a recent popular article, states that he considers dust as one of the greatest enemies of advanced life, since it is the frequent cause of colds and respiratory diseases. He himself has found very frequently, on taking a dusty book from a library shelf, that it gave him a cold in the head. This has occurred so regularly that he now resorts to sponging the dusty edges with a solution of carbolic acid before disturbing the deposit.

THE MANIFESTATIONS OF PARANOIA.*

By ALBERT WARREN FERRIS, A.M., M.D.,

NEW YORK.

When Mendel, in 1881, substituted for "Verrücktheit" the term Paranoia, order should have been evolved out of chaos. The confusion with which the word "monomania" had been surrounded had resulted in the assignment to a place under its sheltering wings of a great variety of tendencies, phobias, and manias. The expression monomania sank from the position designed for it by Esquirol to the level of a popular term for insignificant symptoms, absolutely bereft of any definite clinical foundation.

The word paranoia should have been an individual distillate from a crude, commingled mass. Well-defined lines should have been drawn, and severe elimination should have been practised, with the result of grouping certain delusional insanities alone under the new term. But while eagerly appropriated, the term was employed by individual psychiatrists in varying ways, as determined by personal equation. Its limits were narrowed or its boundaries were separated more widely, according to individual taste. Like the poor traveler in the hands of the Attic robber Procrustes, it was stretched to fit one bed or cut down and wedged into another, until to-day there is as much misuse of the designation paranoia as there was of the term monomania twenty-five years ago.

A psychiatrist to-day runs the risk of being very unpopular if he makes a diagnosis of paranoia without a modifying adjective, and he is told with considerable severity that in Kräpelin's Hospital in Munich there are only about two patients labeled paranoiacs out of a total of two hundred. Mendel himself, so far from being of assistance at this juncture, leads us into a tangled jungle of rudimentary paranoias, paranoias with paranoiac stages, primitive paranoias, and the like, from which we emerge bewildered.

The difficulty seems to have lain in the fact that there has been an error made in the limitation of the field, through losing sight of the most decisive feature of the delusional insanities under consideration. The presence of the delusion of conspiracy or persecution seems to have proved so interesting as to have diverted one's gaze from the important and essential fact. It is not the character of the delusion, but the systematization of the delusions that decides for paranoia. A definite fixed idea, resulting from imagination or defective judgment or defective memory, becomes the central point about which delusions are grouped methodically and systematically, minor replacements of the original delusions frequently occurring without disturbance of the correlation of the notions which seem to the patient logically interdependent.

The delusions are very frequently persecutory, but it is not essential that they should be of such a character. And it is apparently due to the belief that persecutory delusions are pathognomonic of paranoia that alcoholism and even neurasthenia have been mistaken for it, and that so many different conditions have been grouped under the term as to detract from its value.

As has often been said, the decisive characteristics of paranoia are as follows: (1) The unchangeableness of the fundamental fixed idea; (2) the firm belief of the patient in his delusions; (3) the apparent (though unreal) logic of the delusional system; (4) the suddenness and intensity of the reactions; (5) the frequency of false interpretations; (6) the preservation for years of an intellect comparatively unimpaired, though dominated by delusion.

Besides these essentials, there are in most cases interesting additional features, such as *expansive delusions*, the patient believing he is possessed of special charms, unusual strength, and remarkable influence, attributes which constitute the reason for the envy, malice, and persecution by others that exist in his imagination. Closely connected with these ideas is the feeling of *self-importance*, on which is easily grafted a change of personality, producing the familiar reincarnation of an Old Testament notable, of a former sovereign, or of a military celebrity, etc. It is of common occurrence for a paranoiac to look back many years and interpret trivial occurrences of his childhood as significant of his importance and superiority or of a conspiracy against him at that time.

More nearly to complete this slight sketch of paranoia, we must allude to the well-known erotic and religious features, one of which so often forms part of the delusional complex.

We must mention also the presence of hallucinations, which are generally a prominent feature at some time during the development of the psychosis, and which constitute a very important source for the origin and expansion of delusions. The most frequent variety is the hallucination of hearing, and it is very vivid and insistent. Most patients state that single words or short sentences are uttered in their hearing by strangers, servants, passersby, or by some unseen person in the next room; and the utterances consist, they claim, of profane or obscene epithets, scornful, or accusatory remarks, or a leading word or two which indicate to the patient's mind that his whole history, as well as his innermost thoughts, are publicly known. In some cases directions for the action and conduct of the patient are given him in this way, and he obeys. Hallucinations of vision, smell, and touch are less frequent.

It is difficult for us to reconcile with our experiences the statement that some of the foreign psychiatrists make to the effect that in paranoia hallucinations are absent, or at least extremely rare, for in our American experience they seem to be the most uncommon cases of paranoia in which hallucinations are absent.

A diversity of opinion seems to exist also with regard to the development of this psychosis. Magnan states with succinct emphasis that chronic delusional insanity of systematic evolution is never connected with hereditary or acquired predisposition.

On the other hand, Kraft-Ebing says: "I have never seen paranoia in untainted persons. The taint in the vast majority of cases has been hereditary (abnormal character, psychoses, constitutional neuroses, drunkenness in ancestors)."

Spitzka, in defining paranoia, states that it is "based on an acquired or transmitted neurodegenerative taint."

From Bianchi we quote: "True paranoia . . . is a constitutional malady that has its foundation in an anomalous psychopathic structure."

De Fursac says: "Reasoning insanity is to be looked upon as the development of a morbid germ, the existence of which manifests itself in early life by anomalies of character."

Kräpelin says concerning paranoia (Dieffendorf's translation): "It develops on a defective constitutional basis, either congenital or acquired, defective heredity existing in a very large percentage of cases. Peculiar traits and eccentricities may be recognized early in life."

*Read at a meeting of the Section on Neurology and Psychiatry, New York Academy of Medicine.

Frederick Peterson makes the following statement: "There are hereditary taints; some eccentricities in childhood; more marked peculiarities during youth, often associated with a degree of hypochondriasis."

Bruce, treating of "delusional insanity, described on the continent and in America as paranoia," says: "The universally accepted predisposing cause is hereditary predisposition to mental disease which occurs in over 50 per cent. of the cases affected."

It is the writer's experience that in every case which he has treated, or whose history he has read, there has been an anamnesis of peculiarity in taste, habits, and conduct during the youth of the patient, whenever any reliable or complete history of that period in the patient's life has been obtainable.

A satisfactory early history is a difficult thing to obtain. It is rarely the duty of the school teacher to examine into the eccentricities of young pupils. Unfortunately, the majority of parents are negligent or are not intelligently observant. For example, they fail to see a difference between the boastfulness of youth and the mingled arrogance and suspicion of an anomalous mind, and fail to be concerned with marked eccentricity.

The early manifestations of paranoia include irritability with excitement, studied disobedience, outward hostility, moodiness, desire for seclusion, perverted sexual instincts, dreamy indolence, a belief by the patient that he is misunderstood or slighted or not treated with as much consideration as the other children of the family, inordinate satisfaction with his own opinion, and a habit of demonstrating others' inferiority; periods of depression, possibly precocity. Such a syndrome of symptoms occurring in a youth should arouse the parents or tutor to a feeling of alarm, and open their eyes to the fact that, if not already present, there is a possibility of the development of mental disorder. It is clearly evident that excessive stimulation of the cortical cells of the brain should be avoided in such a child. He should be protected from the fatigue incident to long school hours, study at night, competitive examinations, children's parties, and exhausting games, as well as from improper food and indigestion.

Allen Starr has wisely said, in discussing neurasthenia: "Every act of mind or body is attended by certain chemical and physical changes in the cells of the part of the nervous system controlling the act. These go on for a time within physiological limits without harm. But, if continued beyond those limits, they result in exhaustion of the cells, giving rise to uncomfortable sensations of fatigue, and inability to continue work. The initial state of the cells, their degree of development, their inherent strength, and their state of nutrition determine the limit of their endurance . . . . their capacity for recuperation differing widely."

The constitution of the child should be studied in the light of his heredity, and the proper training, education, and environment should be secured for him. Unaided, the average parent and the average teacher cannot make the necessary special study and institute the proper measures for battling with heredity, and for avoiding the fatigue that makes its impress upon the nerve cell. The backward and the precocious, the "strange" or suspicious child, the sullen little anarchist, and the unusually emotional child should be placed in the care of the psychiatrist, and he alone should decide concerning the individual case how much concentration of mind is safe without fatigue, under the daily variation of mental power; what so-called recreations must be forbidden as only varieties of fatiguing effort, and what leaks of nervous and mental energy must be stopped.

No one can positively affirm that the safeguarding and guidance I suggest can prevent the development of paranoia. But no one can deny that some agencies intervene in the mental growth of certain youths with the result of producing atypical or imperfectly developed paranoiacs. These individuals (called "*formes frustes* of paranoia" by Peterson) are always eccentric, and never agreeable or desirable people, and are popularly called "cranks." But at least they are self-supporting members of society, and not homicidal or otherwise dangerous.

If such abortive cases of delusional insanity result fortuitously, ordinary ethics demand the application of the advanced science and skill of to-day in an attempt designedly to control psychopathic tendencies.

The reports of recovery from paranoia must be viewed with extreme suspicion. The disciplinary routine and the regularity of life as to eating, sleeping, exercise, and recreation incidental to custodial care in a proper hospital exercise a very beneficial effect on the disease, and one of great value in modifying it. But the affection is incurable. The few cases that are reported as cured, and that have even been legally rehabilitated as sane people because of the absence of former delusions, should be under constant observation until their delusions return or dementia supervenes.

The medicolegal importance of paranoia is undeniable. With a perfect memory and an intellect unimpaired for many years (except in so far as to be unable to see the force of valid argument, and to perceive the absurdity of his fixed idea), the average paranoiac is plausible and convincing to the layman. He is lucid on all points unconnected with or unrelated to the central idea or the delusional system. He can carry on a business or practise a profession. If wealthy, and without occupation, he can travel, engage in sports, take part in social activities, and order his daily life much as any sane person, unless his delusions involve some of these avocations. The irritability and suspicion that such a person may betray, and the unreasonableness of some acts, are attributed to the ordinary eccentricity of a selfish person. He is acute enough to appreciate that certain statements do not convince his hearers, and may either insist upon them vehemently or abandon the attempt at argument and preserve silence concerning certain delusions.

If under arrest, charged with crime, he may in the main act rationally, for few of the acts of a paranoiac are insane acts; but many anomalies of conduct and speech, as well as frequent irrationalities in correspondence, will certainly betray his condition to the eye of one who is competent to observe.

He of all insane persons illustrates the fallacy of the legal dictum that everyone is sane who knows the nature and quality of his acts, and knows if they are right or wrong. Believing his standard is higher than the statute, and that the law forbidding him to do what he is prompted to do is an unjust law, and therefore may be disobeyed, he reacts promptly to impulse and even calmly commits crime.

Insanity, as psychiatrists have so often insisted, is a medical and not a legal matter. The paranoiac criminal is irrational and irresponsible. While he should not be punished as if sane, he should be placed irrevocably under custodial care for life.

Toothache.—Very small doses of nitroglycerin are asserted to give at least temporary relief in pulsating toothache.—*Medical Council.*

ACUTE INTUSSUSCEPTION.

WITH A REPORT OF A CASE OF SUCCESSFUL RESECTION OF A PORTION OF THE ILEUM FOR GANGRENOUS INTUSSUSCEPTION.*

By JOHN HAMMOND BRADSHAW, M.D.,

ORANGE, N. J.

SURGEON TO THE ORANGE MEMORIAL HOSPITAL, ORANGE, N. J.

This serious affection is fortunately a rare complaint. It may be that it has not been always recognized or has, like appendicitis, been diagnosticated under some other name. The writer in the following investigation has been surprised that its hospital records are not larger. A search through the reports of the Orange Memorial Hospital for the years since 1881 to date shows the records of only eight cases, only two that recovered. These two were cured after laparotomy. In looking up the surgical reports of large metropolitan hospitals, one or two cases a year seem to be about the average number.

In order to present the subject before us, I will first read the histories of two cases that occurred in my own practice last year. Both were treated by abdominal section and both recovered. They are especially interesting, as they represent the two chief types of the disease, the first being the case of an infant under one year of age with a reducible intussusception, the second the case of a child of thirteen with irreducible gangrenous invagination, calling for resection of the gut.

Case I.—Baby Millman, age ten months. This child was referred to my service at Memorial Hospital, Orange, on March 14, 1906, by Dr. H. A. Pulsford. The infant had a history of being sick thirty-six hours. The symptoms were characteristic of intussusception. An elongated tumor could be felt in the right side of the abdomen. Under chloroform narcosis an immediate laparotomy was performed, the incision being made through the right rectus muscle. The tumor proved to be an intussusception of the ileocecal variety—the apex of which passed into the transverse colon and under the liver. It was reduced with difficulty, the intestine being torn in two places near the cecum. These lacerations were sutured with fine silk. The intestines were replaced as soon as possible and the abdomen closed. The infant was given a hot saline enema. During the operation the child was laid upon a hot water pillow and was surrounded by hot water bottles. Great care was taken in hemostasis. The child was a nursling and the mother was allowed to nurse her baby one hour after the operation. She continued to do so without interruption at regular intervals until the baby was discharged, and this the writer believes was a most important factor in the speedy recovery that ensued.
